Of the classifiable respondents, 7 percent were in the high-risk group, 30 percent were in the middle-risk group, and 63 percent were in the low-risk group (Table 1). Even if all 62 persons who did not answer sexual behavior/drug use questions were considered in the low-risk category, the proportion of high-risk respondents still would be considerably higher than that in other samples, i.e., 6.8 percent in this sample compared to 2 percent in the Hispanic population,[6] 4 percent in the Black population,[7] and 3 percent in the general population.[4]

The knowledge level of the sample does not differ markedly from that of the general population as reported by the NHIS for December 1988,[4] (Table 2). Other unpublished surveys in selected Indian populations have produced similar results in terms of knowledge (Steven Helgerson, personal communication, November 7, 1989). As has been found in other samples, respondents' knowledge is better about specific clinical properties of the disease than knowledge concerning transmission.[1,8]

Discussion

The American Indian population of the Pacific Northwest is at potential risk for high rates of HIV infection not only because of the relatively large numbers in high-risk groups but because of the large numbers of youth in the middle-risk group and the small size of many of its 39 tribes. The middle-risk group is predominantly young and male (42.9 percent of males as opposed to 25.3 percent of females). Use of alcohol and illicit drugs is much higher among middle-risk

TABLE 2—Percentage of Correct Answers to Selected Knowledge Questions by NHIS and Northwest Indian Samples

	NHIS December 1988[4]		Northwest Indian Sample				
Questions	Male	Female	Male	Female	Low-Risk	Medium-Risk	High-Risk
1. AIDS is a disease caused by a virus[a]	85	79	83	78	78	80	77
2. Any person with the AIDS virus can pass it on to someone else during sexual intercourse.[a]	95	96	95	96	97	91	98
3. A pregnant woman who has AIDS can give AIDS to her baby.[a]	94	95	89	94	94	91	90
4. How likely do you think it is that a person will get AIDS or the AIDS virus from the following?							
A. Eating in a restaurant where the cook has AIDS.[b]	45	48	45	46	45	45	34
B. Working near someone with AIDS.[b]	67	66	66	65	66	62	60
C. Being coughed or sneezed on by someone with AIDS.[b]	42	43	43	37	40	35	34

[a]Definitely true or probably true were scored as correct.
[b]Very unlikely or definitely not possible were scored as correct.

group members than among those in the low-risk group.[5] Middle-risk group members reported their first sexual experience at a younger age than those in either the high- or low-risk group, and women in the middle- and high-risk group who have had pregnancies were younger at the time of their first pregnancy than those in the low-risk group.[5] Finally, over half of the middle-risk group, compared to 13 percent of low-risk and 41 percent of high-risk groups, reported having sexual partners from both reservation and non-reservation communities. If introduced into one of the small reservation communities, HIV could decimate the population.

ACKNOWLEDGMENTS

Funding from the Indian Health Service, the Northwest Portland Area Indian Health Board, the State of Idaho, and the State of Oregon, is acknowledged with gratitude. The comments of Jillene Lamb and the assistance of Claire Younger in manuscript preparation are appreciated. We acknowledge, with appreciation, the help of Steven Helgerson, IHS epidemiologist, in obtaining information on other studies in Indian populations.

Steady Increase Reported in Health Personnel; Shortages Persist among Nurses, Minorities

Despite recent declines in the numbers of health professions school graduates, the United States supply of active health personnel has risen steadily since 1970, and ratios of health personnel to population are currently at their highest levels, according to a recent report from the Health Resources and Services Administration (HRSA). In submitting the report to the Congress, Health and Human Services Secretary Louis W. Sullivan warned that, "While the numbers generally show that we have a strong foundation to meet personnel requirements through the end of the century, they also reveal problems that will continue to demand our attention." Highlights of the report include the following:

- Black and Hispanic physicians constitute only 3 percent each of the total physician supply, while Blacks account for 12 percent of the total US population and Hispanics for 7 percent. First-year and total enrollments of minorities in health professions schools have not changed significantly in recent years, and Black enrollment has shown less increase than other minority groups.
- The smaller graduating classes and continuing exits from the health work force are expected to impact on the field between the years 2000 and 2020. Growth in the supply of many health professions, such as nursing and dentistry, is expected to slow.
- A national shortage of registered nurses exists despite growth in the supply from 750,000 in 1970 to more than 1.6 million in 1988. Although the active supply will continue to increase over the next 15 years, the present shortage evokes concern about projections of a smaller supply of nurses in the future.
- More primary care practitioners are needed to provide services for patients in their initial contact with the health care system, and to address rural and inner-city health problems as well as promote health enhancement and illness prevention.
- Recent studies and surveys also reveal shortages of personnel in public health, allied health, geriatrics and gerontology, the report noted.

More information on the report, *Seventh Report to the President and Congress of Health Personnel in the United States*, is availabie from the Office of Data Analysis and Management, Bureau of Health Professions, Room 8-47, HRSA, 5600 Fishers Lane, Rockville, MD 20857. Tel: 301/443-6936.

Commentary

The Federal Environmental Health Workforce in the United States

KEN SEXTON, ScD, AND SUSAN A. PERLIN, ScD

Abstract: This paper summarizes existing data on the size and composition of the federal environmental health workforce, delineates the major categories of activities carried out by its members, identifies current and emerging issues that are likely to affect workforce activities, and makes qualitative inferences about future trends and directions. Findings suggest that there is a current and future need for more and better qualified professionals in the federal environmental health workforce. (*Am J Public Health* 1990; 80:913–920.)

Introduction

The United States federal government has responsibility for protecting the public from the adverse consequences of exposure to potentially harmful environmental agents. The importance of the nation's environmental health has been recognized during the past 20 years, as evidenced by the passage of more than a dozen major environmental laws and subsequent amendments, including the: Clear Air Act; Safe Drinking Water Act; Toxic Substances Control Act; Federal Insecticide, Fungicide, and Rodenticide Act; Resource Conservation and Recovery Act; and Comprehensive Environmental Response and Compensation Act ("Superfund").

The federal government is the single largest employer of environmental health professionals in the United States. Although the Environmental Protection Agency (EPA) has the lead role in administering and enforcing many environmental laws, other federal agencies, such as the Public Health Service (PHS) and the Occupational Safety and Health Administration (OSHA), also have direct statutory authority or involvement in environmental health issues. Moreover, many environmental health professionals are employed by federal agencies whose primary mission is not related directly to the protection of environmental health (e.g., the Department of Defense). Major Executive Branch agencies with environmental responsibilities are shown in Figure 1.

Attempts to evaluate the environmental health workforce, federal and otherwise, are a relatively recent development.[1–6] Owing to a variety of factors, there is little consensus about its size and composition. Among the problems are the absence of a generally accepted definition for environmental health, disagreement about the discrete specialties that comprise the workforce, the diversity of job titles within the field, the wide variety of responsibilities and programs in environmental health, differing employers, and the varied professional/technical/administrative skills required in different environmental health settings.[1–2]

Our objective is to examine the federal environmental health workforce by using available information and to draw qualitative inferences about current and future directions. It is important to note that we specifically exclude members of the Armed Services from our analysis. Although there are certainly a substantial number of environmental health professionals contained therein, obtaining objective data on their number and function is problematic.

The Existing Skills Mix

The federal environmental health workforce is defined broadly to include all civilian members of the federal government and the Commissioned Corps of the Public Health Service, whose primary duties and responsibilities are the identification, assessment, management, communication, or remediation of human health risks that result from environmental factors. This definition encompasses a diverse group of professionals, trained in a multitude of academic disciplines, and focusing on a wide variety of issues. Among the myriad of problems addressed by the environmental health workforce are air quality, water quality, food protection, vector control, waste management and control, consumer protection, noise control, and general environmental health issues, including direct and indirect effects on human health from ecological changes.

Within the federal government, all civilian employees who are not members of the Senior Executive Service (SES) are assigned to a particular civil service job classification series. Many of the job classifications are broadly defined. Thus, a person classified as a Public Health Program Specialist in one agency may have vastly different training, educational background, work experience, and duties and responsibilities than a person with the same classification in another agency, or even in another division within the same agency. The Environmental Protection Specialist classification, for example, which is used to the greatest extent by EPA, is defined so broadly that almost any environmental health professional, and some non-health related professionals, can be so classified.

Toxicology and epidemiology are two academic disciplines that are traditionally considered to be an integral part of the environmental health workforce. Yet until recently, neither specialty was classified as a separate job category within the federal government. Although EPA and other agencies are beginning to reclassify toxicologists into the newly created toxicology series, many are still categorized as Medical Officers, Chemists, Mathematical Statisticians, Environmental Engineers, or General Biological Scientists. Epidemiologists still do not have a separate job title and are classified in a wide variety of series, which vary by agency.

Address reprint requests to Ken Sexton, ScD, Director, Office of Health Research (RD-683) US Environmental Protection Agency, 401 M Street, SW, Washington, DC 20460. Dr. Perlin is a staff scientist in the same office. This paper, submitted to the Journal February 28, 1989, was revised and accepted for publication February 22, 1990.

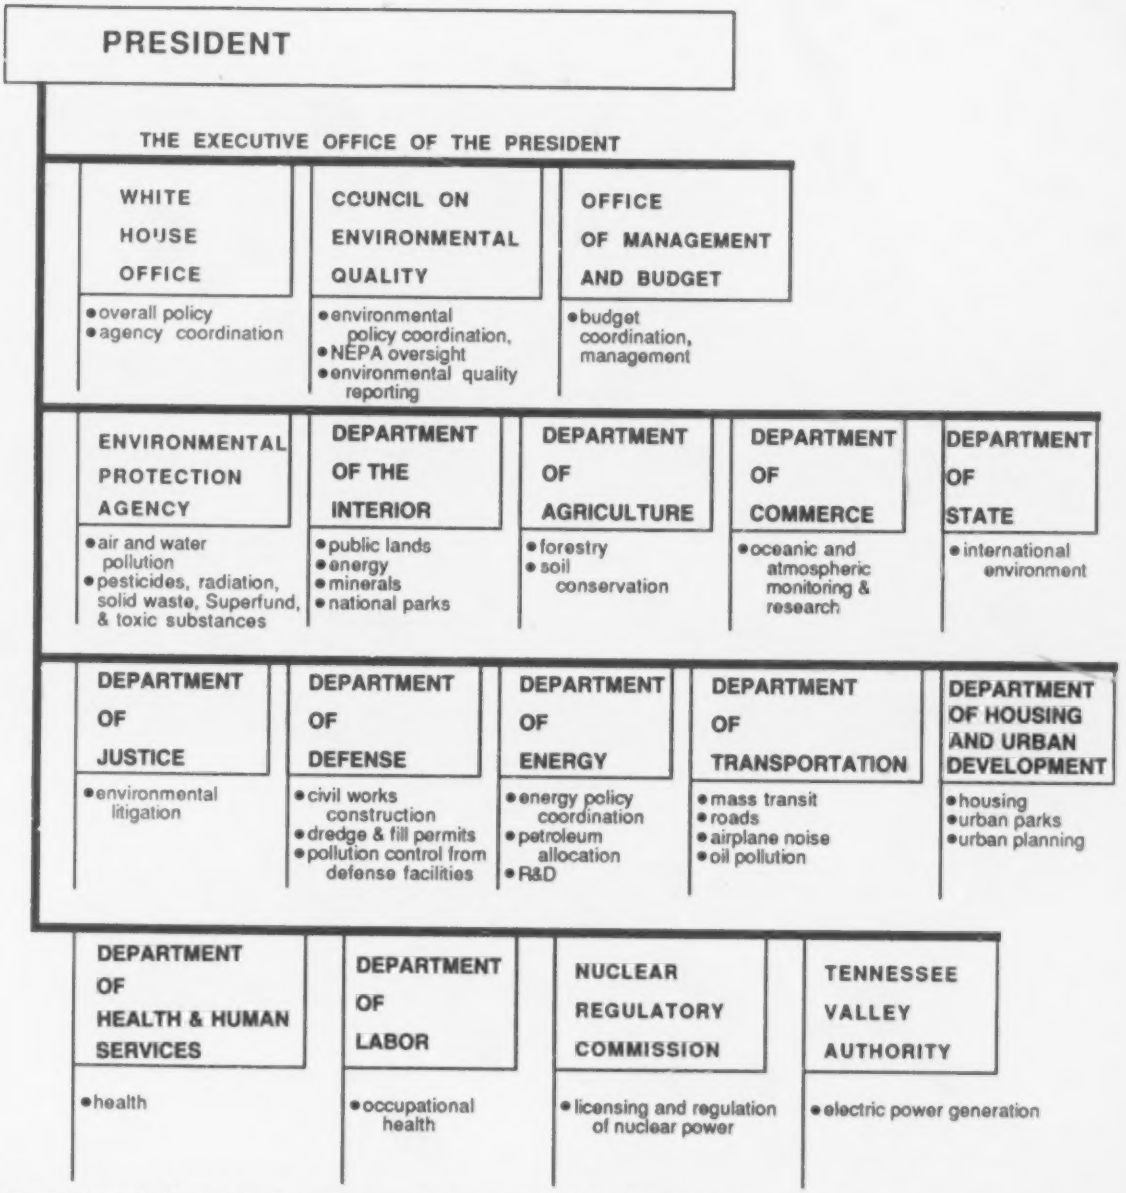

FIGURE 1—Major Executive Branch Agencies with Environmental Responsibilities, United States (adapted from ref. 16).

Keeping these caveats in mind, we used the Civil Service job classifications to examine the current federal environmental health workforce. Data given in Table 1 provide a summary for eight executive branch agencies of the number of civilian employees who are listed in job classifications that we believe are most directly related to environmental health. An indication of their collective contribution to the total number of employees in the selected job categories from across the entire federal government can be inferred from percentage figures in the last column of the table.

These data suggest that there are a substantial number of environmental health jobs in federal agencies whose primary mission is not protection of public health (e.g., Department of Agriculture, Department of Defense), and that, of the 27 job categories listed, most employees (75 percent) fall into one of eight job classifications: Medical Officer, Biological Technician, General Biological Science, Safety Management, Veterinary Medical Science, Environmental Engineer, Microbiology, and Environmental Protection Specialist.

In the entire federal government, the total number of full-time, white collar, civilian workers (excluding the Postal Service) was 1,602,438 as of October 1985. In the same year, the total for EPA, OSHA, and the PHS (three agencies directly involved with environmental health issues) was 60,298. The total number of employees in the 27 environmental health-related job classifications was 28,919 for the

a) All data are current as of 10/31/85 and were provided by the Federal Office of Personnel Management. All figures are based on full-time, white collar, federal civilian workers, excluding the Postal Service.
b) Defense includes only civilian employees of army, navy, air force.
c) Health and Human Services (HHS) has several offices and administrations, including the: Public Health Service (See footnote b, Table 2), Social Security Administration, Office of Human Development Services, US Office of Consumer Affairs, Health Care Financing Administration, and the Family Support Administration.
d) Total employees in each job classification for the eight agencies listed. Figures do not include Commissioned Corps of the Public Health Service.
e) Percentage of the entire federal government workforce for the specific job category, based on full-time, white collar civilian employees, excluding the Postal Service. For example, the 3,079 employees in the eight agencies who are classified in safety management represent 87% of the people in that job series across the whole federal government.
f) Toxicology is a new job series and there were no employees listed in this category as of 10/31/85. The process of reclassifying toxicologists is currently underway in several agencies.
g) The majority of these medical officers are in the Public Health Service, with approximately half directly involved in patient care and half involved in medical research.
h) Total workforce includes all full-time, white collar federal civilian workers for each listed Agency. This includes the workforce for the 27 job classifications listed, plus all other full-time employees, regardless of whether or not they are involved in environmental health-related jobs. This includes all support staff, such as secretaries, budget and personnel staff, and all managers.

eight selected agencies, that is 70 percent of all employees so classified in the federal government as a whole (Table 1).

In Table 1 we did not include more generic classifications, such as chemist, physical scientist, or statistician, because we were less certain that individuals in these categories would be involved in environmental health activities for all of the agencies listed. Nevertheless, individuals so classified and who work in a federal agency that deals primarily with environmental health issues are an important part of the environmental health workforce. Information for 1988 on the number and types of environmental health practitioners (including chemists, physical scientists and statisticians) in eight of the federal agencies most directly responsible for environmental health issues is given in Table 2. For EPA, the addition of six of these generic job categories increased the identified workforce by about 20 percent.

Because of EPA's lead role in many environmental health issues and owing to the relatively large number of environmental health professionals employed therein, Table 3 provides a more detailed description of EPA's environmental health workforce. Considering full-time, part-time, and intermittent employees, about 16 percent are involved directly with research and development; 27 percent are in regulatory offices in Washington, DC where they have responsibility for developing and carrying out environmental laws and regulations; 50 percent are employed in the 10 EPA regional offices where they oversee implementation and enforcement of regulations; and 6 percent provide necessary technical and administrative support.

Current Federal Environmental Health Activities

We categorized all environmental health activities into one or more of four general categories: research and development; risk assessment (including hazard identification); risk management/reduction; and risk communication. A description of these four categories with examples of related activities is provided in Table 4.

Many of the environmental health activities in the federal government are focused on risk assessment and risk management. To aid decision-making, agencies such as EPA, OSHA, and the Food and Drug Administration have developed formal risk assessment procedures for identifying health

a) With the exception of the Public Health Service (PHS), all figures are based on white collar civil service employees, excluding the Commissioned Corps.
b) The *Public Health Service* is an operating division within HHS and includes the following agencies: ATSDR, FDA; NIH (including NIEHS); Alcohol, Drug Abuse and Mental Health Administration; Health Resources and Service Administration; Indian Health Service; Office of the Assistant Secretary of Health; and CDC, which includes the National Institute for Occupational Safety and Health (NIOSH), Center for Environmental Health and Injury Control, Center for Infectious Diseases, Center for Prevention Services, National Center for Health Statistics, Center for Health Promotion and Education, Training and Laboratory Program Office, International Health Program Office, Epidemiology Program Office, and the Office of Program Support.
c) EPA (Environmental Protection Agency), data current as of 12/1/88, provided by the EPA Office of Administration and Resources Management, and represent permanent, full-time, civil service.
d) OSHA (Occupational Safety and Health Administration), data were provided by the OSHA Office of Personnel and are current as of 7/30/89.
e) FDA (Food and Drug Administration), data current as of 4/1/88, provided by the Department of Health and Human Services, Office of the Assistant Secretary for Health.
f) Commissioned Corps of the Public Health Service, irrespective of agency, data current as of 4/1/88 and provided by the Division of Commissioned Personnel.
g) CDC (Centers for Disease Control), data current as of 5/31/88, provided by Personnel Management Office of CDC.
h) NIEHS (National Institute of Environmental Health Sciences), data current as of 5/21/88, provided by personnel office, NIEHS, Research Triangle Park, NC.
i) NIOSH (National Institute for Occupational Safety and Health), data are current as of June 1988, and were provided by the Personnel Management Office of the Centers for Disease Control.
j) ATSDR (Agency for Toxic Substances and Disease Registry), data are current as of June 1988, and were provided by the Personnel Management Office of the Centers for Disease Control.
k) Total workforce refers to all full-time, white collar federal civilian workers for each listed agency, including those people in the 23 job classifications listed, and all other full-time employees including all support staff such as secretaries, budget and personnel staff, and all managers. The only exceptions is PHS, which includes only the Commissioned Corps, and has only degreed scientists, engineers, doctors, etc.

hazards and for estimating the risks to human health posed by products and activities.[7–9] Risk management procedures are employed for weighing policy alternatives and for selecting the most appropriate action by integrating the results of risk assessment with engineering data and with social, economic, and political concerns.[10] The interrelationships among research and development, risk assessment, risk management, risk reduction, and risk communication are depicted schematically in Figure 2.

As shown in Table 3, most of the EPA workforce is involved in the application of scientific data to the resolution of environmental health problems (e.g., risk management and risk reduction).[11] A relatively smaller number is involved directly with data generation (research and development), while a steadily increasing fraction of the workforce is involved in risk assessment and risk communication, a trend that is expected to continue into the foreseeable future.[12–14]

Emerging Environmental Health Issues

Advances in the field of environmental health sciences, introduction of innovative technologies, and promulgation of new environmental regulations are examples of the kinds of activities that can have significant impacts on the future size, composition, and activities of the environmental health workforce. For example, increasing awareness of the potential health hazards associated with municipal and hazardous wastes led to passage of the Resource Conservation and Recovery Act which, in turn, created an expanded need for environmental health practitioners in all aspects of waste management, including collection, transport, storage, treatment, and disposal, as well as stimulating research and development on related health and risk reduction issues.

Attempts have been made to examine the environmental health issues that are likely to be most significant over the next decade or more.[15–25] Some of the more important issues are discussed briefly below.

Detection of Health Effects

Just as environmental monitoring has progressed so that it is now possible to measure pollutant concentrations at the part-per-trillion level, so too must our capabilities to ascertain target tissue concentrations, and to detect effects at the cellular and molecular level be enhanced. Coupled with similar improvements in our understanding of the basic biological mechanisms that underlie health effects, this will allow for greater certainty and accuracy in assessment of environmental health risks.

Molecular epidemiology, the use of biologic indicators to link individual exposure with health outcome, is gradually becoming a reality. Use of these techniques within the context of epidemiologic investigations offers a means to assess health risks more directly and thereby reduce uncertainties.[26,27]

Non-Cancer Health Effects

Current and future research efforts are likely to focus on several non-cancer effects of environmental agents (e.g., pulmonary, cardiovascular, reproductive, developmental, neurologic, immunologic, hepatic, and dermal) to determine which health outcomes are important and in what kinds of situations.[28]

High-Risk Groups

Advances in our understanding of biological predisposition to a particular health effect (e.g., by virtue of age or genetic susceptibility),[29] as well as in our knowledge of human activities and lifestyles that give rise to elevated exposures (e.g., time spent inside a building with air pollution problems)[30,31] will continue to help focus research and regulatory efforts on the appropriate population subgroups. More precise techniques to identify and study populations

a) Figures provided by EPA Office of Administration and Resources Management and are current as of December 1, 1988. Figures represent civil service permanent employees, including full-time, part-time, intermittent, and temporary employees. Full-time employees work 80 hour/2 weeks; part-time employees work less than 80 hour/2 weeks. Intermittent employees work no more than 130 days/year and are primarily advisory board members and consultants. Some consultants are also in the full-time, temporary category.
b) ORD, the Office of Research and Development, is the primary research arm of EPA.
c) OPTS, the Office of Pesticides and Toxic Substances, has primary responsibility for regulating pesticides (under FIFRA, the Federal Insecticide, Fungicide, and Rodenticide Act) and other toxic chemicals (under TSCA, the Toxic Substances Control Act).
d) OSWER, the Office of Solid Waste and Emergency Response, has primary responsibility for administering programs that address hazardous and solid wastes, including the Superfund program, underground storage tanks and active Resource Conservation and Recovery Act (RCRA) facilities.
e) OW, the Office of Water, has primary responsibility for regulating contaminants in drinking water, ground water, and surface water.
f) OAR, the Office of Air and Radiation, has primary responsibility for regulating air emissions under the Clean Air Act and for administering the agency's radiation program.
g) Regions, the 10 regional offices have the primary responsibility of carrying out the various regulations in different areas of the country.
h) Other, includes the Office of the Administrator, and the following offices: Enforcement and Compliance Monitoring, General Counsel, Inspector General, External Affairs, Administration and Resources Management, and Policy, Planning and Evaluation.

that are at higher risk because of either increased susceptibility or elevated exposures are needed.

Health Hazard Identification

Currently, there are several issues and/or technologies for which the hazard identification process is underway, including: human exposure to non-ionizing radiation (particularly Extremely Low Frequency radiation inside residences)[32,33]; non-asbestiform fibers used to replace asbestos in buildings[34]; methanol used as an alternative fuel in motor vehicles[35]; and the release of genetically engineered and naturally occurring microorganisms in conjunction with

TABLE 4—General Categories of Activities Carried out by the US Environmental Health Workforce

Activity Category	Description of Activities	Example Activities
Research and Development	Scientific research and development to generate appropriate data on relevant environmental health issues. The goal is to improve the quantity and quality of the existing data base, as well as to enhance our understanding of basic underlying mechanisms.	Animal toxicology Epidemiology Human clinical research Environmental monitoring
Risk Assessment	Assessment and evaluation of available environmental health data to determine their appropriateness and adequacy for incorporation into decisions about safeguarding public health. The goal is often to develop a quantitative health risk assessment in order to identify and prioritize environmental hazards.	Evaluation of data validity and completeness Hazard identification Risk characterization Development of guidelines (e.g., risk assessment, toxicity testing)
Risk Management and Risk Reduction	The use of environmental health data to make, implement, and enforce policy decisions about protection of public health. The goal is to improve decisions that affect environmental health, reduce public health risks, facilitate implementation of decisions, and enhance enforcement activities.	Policy and regulatory decisions Pollution prevention, control, and remediation Enforcement and compliance activities Promulgation of testing guidelines
Risk Communication	Communication of the risks associated with exposures to environmental agents, as well as the scientific basis for risk management decisions. The goal is to provide environmental health practitioners and the public with usable and understandable information about environmental health issues.	Technology and information transfer Explanation of scientific basis for decisions Implementation of "Public Right-to-Know" laws Communication of the health significance of environmental exposures

the burgeoning biotechnology industry.[36,37] Both research and regulatory decisions will be affected by the outcome of these and other hazard assessment activities.

Pollution Prevention

Historically, EPA has emphasized the use of pollution control equipment to reduce health and environmental risks (e.g., stack scrubbers for SO_x, tailpipe catalysts for automotive emissions). Informally known as "end-of-pipe" controls, these measures focus on reducing pollutant emissions after they have been generated. As we move into the 1990s, however, it is becoming increasingly apparent that many environmental health problems are not amenable to this approach. Indoor air pollution, global warming, and runoff from farms and construction sites are examples of problems that are not readily solved by these traditional approaches. Thus, it is imperative that EPA and other environmental health agencies develop strategies that prevent or reduce pollution before it is generated. In the future, increasing emphasis will be placed on innovative approaches to pollution control, which include minimizing the amount of wastes generated as well as recycling or reusing those that are produced.[22]

Future Outlook

Many factors suggest an expanding requirement for environmental health professionals: the potential health hazards associated with commercialization of new technologies (e.g. superconductors); continued efforts to evaluate and control previously identified health hazards (e.g., asbestos, radon, lead, ozone, and dioxin); ongoing attempts to characterize and mitigate the health risks associated with tens of thousands of chemicals in our environment; expanding knowledge about the subtle health effects resulting from exposures to the complex mixture of pollutants in our daily environment; and increasing concerns about the potential for adverse health effects from environmental changes, such as global warming and stratospheric ozone depletion.[15–22] Studies indicate that there is already an inadequate supply of people with appropriate education and training.[1–6,22] It seems highly probable that the shortage will become even more acute unless adequate steps are taken to rectify the situation. Despite the fact that detailed analyses are precluded by a lack of objective data, certain trends in educational and training needs seem readily apparent.

- Regardless of their specific job, members of the environmental health workforce need a firm grounding in the general principles of public health, as well as an appreciation of the rudiments of health and ecological sciences. In addition, familiarity with risk assessment and risk management procedures is increasingly important.
- It has become clear that many environmental health problems are not limited to a single medium (e.g., air, waste, soil) and therefore require multimedia and multidisciplinary approaches to understand and reduce associated risks. Thus, there will be a premium on individuals who appreciate and understand the complex interactions underlying environmental hazards, and who have the interpersonal skills to function effectively as part of a multidisciplinary team.
- The requirement for professional risk assessors and risk managers will become more acute as environmental problems escalate from local concerns to national and international issues. The economic and social ramifications of addressing these issues demand that we apply informed decision-making based on adequate scientific information about the relationships between human exposures and associated health effects.

- There is an obvious need to train medical doctors so they can effectively recognize and treat environmentally induced disease (e.g., chemical sensitivity).
- A large growth in demand is likely for qualified environmental health experts who can effectively communicate the risks of environmental exposures, as well as the associated uncertainties, to nonscientists.
- There will be a continuing and probably expanding requirement for qualified environmental health professionals capable of performing relevant research and development activities. Among the professionals who are likely to be in greatest demand are epidemiologists, biostatisticians, environmental engineers and chemists, toxicologists, and mathematical modelers (e.g., environmental fate and transport models, pharmacokinetic models).
- A general knowledge of the history of environmental health, particularly in the 20th century, as well as familiarity with the major environmental laws is becoming a requirement for many environmental health professionals working in federal agencies.

In summary, there is a current shortage and a projected demand for more and better qualified professionals in the federal environmental health workforce. These needs can only be addressed if we acknowledge the problems and take appropriate, timely steps to educate, train, recruit, and retain environmental health professionals in the federal government.

Environmental and Biological Monitoring for Lead Exposure in California Workplaces

LINDA RUDOLPH, MD, DAN S. SHARP, MD, STEVEN SAMUELS, PHD, CARIN PERKINS, MS, AND JON ROSENBERG, MD

Abstract: Patterns of environmental and biological monitoring for lead exposure were surveyed in lead-using industries in California. Employer self-reporting indicates a large proportion of potentially lead-exposed workers have never participated in a monitoring program. Only 2.6 percent of facilities have done environmental monitoring for lead, and only 1.4 percent have routine biological monitoring programs. Monitoring practices vary by size of facility, with higher proportions in industries in which larger facilities predominate. Almost 80 percent of battery manufacturing employees work in job classifications which have been monitored, versus only 1 percent of radiator-repair workers. These findings suggest that laboratory-based surveillance for occupational lead poisoning may seriously underestimate the true number of lead poisoned workers and raise serious questions regarding compliance with key elements of the OSHA Lead Standard. (*Am J Public Health* 1990; 80:921–925.)

Introduction

The United States Public Health Service goals for 1990 include the virtual elimination of occupational heavy metal poisoning.[1] Ability to assess the extent to which occupational health programs are effective in achieving this goal rests on the existence of an adequate surveillance system.[2] Adult lead poisoning is virtually always associated with work and is due to a single causative agent. Because early lead toxicity is reversible, and patients may be asymptomatic or have vague symptoms, biological monitoring for lead by analysis of blood lead levels is particularly useful.[3] Biological and environmental monitoring for lead are well-established, and required by the California and federal Occupational Safety and Health Administration (OSHA) Lead Standards.[4] California now requires laboratories to report elevated blood lead levels to the State Department of Health Services.[5]

However, little is known regarding what proportion of workers at risk of lead exposure participate in a biological monitoring program that would allow them to be identified through a laboratory-based surveillance system. Although index cases could be identified if even a small proportion of workers were monitored, a laboratory-based system with low sensitivity would reduce the ability to evaluate the true magnitude of the problem, identify trends, and/or properly target or evaluate interventions. An estimate of the sensitivity—or ability to identify workers with elevated blood levels—of such a laboratory-based system is important, if registry data are to be used for monitoring trends or targeting interventions.

The goals of the survey herein reported were to assess monitoring practices for lead exposure in California work sites, and to evaluate the extent to which a laboratory-based occupational lead poisoning surveillance system would fulfill surveillance functions.

Methods

Selection of Sample

Four pre-existing data bases were used to identify 505 unique four-digit Standard Industrial Codes (S/C) with potential for lead use: the National Institute for Occupational Safety and Health (NIOSH) National Occupational Hazard Survey 1972–74 (NOHS)[6]; federal OSHA inspections, 1979–82, provided by Dr. John Froines (UCLA) from federal OSHA Management Information Service Data; Cal/OSHA Lead Standard violators, 1979–85, provided by the California Department of Industrial Relations; and the New York Heavy Metals Registry, 1981–85.[7] A list of employers in California in these SIC codes was obtained from the California State Employment Development Department[8]; these 236,564 reporting facilities, employing 5,837,156 individuals, comprised the sampling frame for the survey.

A weighted sampling scheme, designed to be free of systematic bias, was used to enrich the survey sample with lead-using industries[9]: seven SIC codes were selected as "special interest" industries based on past evidence of high levels of ambient lead and high proportions of workers exposed. The remaining codes were categorized into 165 "high" and 333 "low" exposure groups, based on either federal OSHA inspection data, or judgment of experienced industrial hygienists. Facilities were stratified by total number of employees. The predicted number of lead-exposed workers at each facility was estimated, based on NOHS data on the proportion of exposed workers in each SIC code. Sampling with probability proportional to size[10] was conducted, using predicted numbers of lead-exposed workers as the measure of size.

Survey of Employers

Information was obtained from employers through two questionnaires administered by mail and telephone interview. The initial questionnaire was designed to identify the presence or absence of lead use, the total number of employees at the facility, and a contact name for the second questionnaire. The second questionnaire was administered only to those employers reporting lead use, and requested a list of all processes involving lead use at the facility, the number of workers involved in each process, and information about environmental and biological monitoring practices at the facility.

Categorizing Survey Responses

Lead-using processes described by employers were categorized into 12 specific processes, and three more general exposure categories (high/medium/low) based on anticipated level and frequency of exposure as judged by eight experienced industrial hygienists. It should be noted that the exposure categories utilized in the analysis were *independent*

of the SIC categories in the initial sampling scheme. Responses were also categorized by facility size and unionization.

Analysis

The statistical analysis incorporated information on the weighted sampling scheme to produce valid and unbiased statewide estimates of numbers and percentages.[11] The standard errors for each estimate reflect the variability that arose from taking a sample; estimation of small numbers frequently leads to large relative standard errors.

Results

Response Rates

Of the 1,165 unique facilities in the initial sample, 1,089 (93.5 percent) completed the first questionnaire. Of these, 539 employers reported using lead or lead-containing materials and 521 (96.7 percent) of this group completed the second questionnaire.

Occupational Lead Exposure

In California, 52,700 facilities (7.7 percent of all facilities) were estimated to use lead. An estimated 230,000 employees work in positions in which their employers report a lead-using process. This represents almost 2 percent of California's total work force.

Environmental Monitoring

Only 2.6 percent of facilities engaged in lead-using processes were estimated to have ever done any environmental monitoring for lead. These facilities employed an estimated 205,000 workers, 10.7 percent of California workers exposed to lead. The proportion of facilities with environmental monitoring varies directly with the number of employees (Table 1).

The percent of potentially exposed employees in positions which have had environmental monitoring performed varies according to lead-using process (Table 2). For example, less than 1 percent of workers soldering pipes or painting with lead-based paints worked in monitored positions, in contrast to 80 percent of battery manufacturing workers.

In general, the proportions of employees in monitored positions are higher in unionized than non-unionized facilities; this was not true in the 100–499 employee size category, perhaps due to the large number of monitored non-unionized electronics industry solderers in this size category (data available on request to author).

TABLE 1—Estimated Number of Facilities with Lead Use in California, and Estimated Number with any Environmental Monitoring of Exposure to Lead, by Facility Size

Facility Size	Facilities with lead use N	Facilities with any environmental monitoring N	Facilities with any environmental monitoring % (SE)
1–19 employees	33,410	32	0.10 (0.04)
20–99 employees	12,753	292	2.29 (1.23)
100–499 employees	4,112	405	9.85 (4.10)
500 or more employees	2,402	630	26.22 (7.12)
Total	52,677	1,359	2.58

Of those workers with high/daily exposures, 37 percent work in positions which had been monitored, versus only 2.6 percent in positions with high/weekly exposures. Radiator repair was the most commonly reported process with high/daily exposures for which environmental monitoring had never been performed.

The characteristics of process, size, and unionization appear to be interrelated. For example, an estimated 88 percent of radiator repair employees work in small (1–19 employees) facilities, while 87 percent of battery manufacture workers are employed in larger (100–499 employees) facilities. Less than .6 percent of the smallest facilities' workers are unionized, versus nearly 50 percent of those at the largest size facilities. A significant proportion of environmental monitoring appears to be done by company-employed industrial hygienists. At large facilities, this was true for 80 percent of monitored workers. For the smallest companies, about 57 percent of monitoring was conducted by private contractor, 19.7 percent by insurance companies, and 23.2 percent by Cal-OSHA (compliance or consultation). Less than one-half of monitored positions had been evaluated in the year preceding the survey; in over 17 percent, monitoring was most recently performed in 1980.

Biological Monitoring

Only 1.4 percent of facilities engaged in lead-using processes, and about 2.6 percent of potentially lead-exposed workers were estimated to have routine biological monitoring programs. Marked variation in biological monitoring practices was noted among the seven "special interest" SIC groups (Table 3). Fifty-three percent of the blood lead analyses performed as part of routine biological monitoring programs are performed by California laboratories, with the rest being done by out-of-state laboratories. The proportion of employees receiving biological monitoring varies with size of facility and potential for high lead exposures (Table 4).

Discussion

There are several possible limitations in the methodology employed in this survey. Results were based exclusively on data from employer self-reporting of lead use, number of workers exposed, and monitoring practices. No attempts were made to validate the information received from employers.

It is possible that some employers did not report actual use of lead on the first survey, and were subsequently excluded; this should not have led to an underestimate of the proportion of workers monitored.

Workers conducting different job activities may have been lumped together as "monitored", even if only one activity in an area has actually been assessed. Also, full- and part-time workers may have been lumped together. Some battery manufacturers included clerical workers among those potentially exposed. In several facilities, these employees received biological monitoring, but none of their positions were environmentally monitored. This may explain discrepancies between environmental and biological monitoring prevalence (e.g., 79 percent of battery workers are in environmentally monitored positions, while 95 percent are biologically monitored).

In the absence of actual exposure data for each work site, the extent to which monitoring actually should be conducted in the sampled facilities cannot be determined. It is possible that monitoring was not done because exposures are below those levels that warrant it. Although our survey

TABLE 2—Estimated Number of Lead-exposed Employees, by Occurrence of Environmental Monitoring at any Time in the Past by Type of Lead-using Process

Lead-using Process	Employee working in position where environmental monitoring ever done? Yes N	Yes % (SE)	No N	No % (SE)	Total employees exposed to lead N
Soldering, except pipes and sheets	18,931	16.59 (3.98)	95,169	83.41 (3.98)	114,100
Dispensing leaded gasoline	129	0.42 (.42)	30,829	99.58 (0.43)	30,958
Soldering pipes and sheets	116	0.52 (0.31)	22,234	99.48 (0.31)	22,350
Cable cutting and splicing	374	2.72 (3.52)	13,393	97.28 (3.52)	13,767
Painting with lead-based paint	92	0.72 (0.53)	12,601	99.28 (0.53)	12,693
Painting with lead-based inks	0	0	7,496	100.00	7,496
Casting or melting lead or jointing	975	21.71 (7.86)	3,517	78.29 (7.86)	4,492
Radiator repair[a]	49	1.14 (0.79)	4,271	98.86 (0.79)	4,320
Welding metal alloys or surfaces painted with lead based paints	280	6.79 (2.55)	3,844	93.21 (2.55)	4,124
Machining, grinding or sanding surfaces painted with leaded paints	254	7.92 (7.23)	2,954	92.08 (7.23)	3,208
Battery manufacture	1,477	79.62 (8.65)	378	20.38 (8.65)	1,855
Other process with lead use	1,814	18.01 (6.41)	8,258	81.99 (6.41)	10,072
Total	24,491	10.67	204,944	89.33	229,435

[a]Includes workers in SICs 7528 and 7539

instrument did not directly assess this possibility, it seems unlikely that this would be true in the "high" exposure categories. There is no evidence that workers in smaller facilities are likely to have lower exposure than those in larger plants, suggesting that the lack of monitoring in small facilities is due to factors other than lack of exposure.

Few other data on biological and environmental monitoring are available. Ratcliff, Halperin, *et al.*[12] utilized data from NOHS to demonstrate that there is no consistent evidence that workers potentially exposed to chemical hazards are more likely to receive screening than other workers, but that such screening is more likely in large facilities. This is consistent with the results of the current survey.

However, the NIOSH study estimated that almost 25 percent of lead-exposed workers receive periodic monitoring, and that 18 percent receive blood tests—a substantially higher proportion than seen in this survey. The NOHS survey was done prior to promulgation of the OSHA Lead Standard; it asks about any blood test, without reference to specific biological monitoring for a particular substance. Also, the NOHS appears to have counted all employees as receiving blood tests if any did.[6] In contrast, the current study asked about monitoring in workers specifically identified as working in lead-using jobs. Therefore, the results reported here are likely to constitute a more accurate assessment of monitoring for lead in lead-exposed workers.

The lack of environmental or biological monitoring in a majority of potentially lead-exposed workers may result in inability to identify workers or work sites where interventions could prevent cases of occupational lead poisoning. The widespread lack of monitoring makes surveillance for trends, assessment of the true magnitude of the problem, or evaluation of the efficacy of interventions virtually impossible. A laboratory-based surveillance system for lead over-exposure would be limited to the identification of two categories of workers: those with overt clinical signs of lead poisoning for whom an alert clinician has ordered a blood lead test, and the small minority of workers who participate in a routine monitoring program. These categories are likely to represent two extremes: the very worst cases, and those who are likely to have more access to medical and industrial hygiene services by virtue of being enrolled in a monitoring program. The large majority of lead-exposed workers remain excluded, and thus inaccessible to the surveillance system.

These limitations do not undercut the ability of a laboratory-based surveillance system to identify important index cases of lead poisoning.[13]

Our data imply a significant lack of compliance with the monitoring provisions of the OSHA Lead Standard, which were constructed specifically to facilitate timely interventions. The relatively high prevalence of monitoring in battery manufacture may be attributable to past California OSHA compliance efforts specifically directed at biological monitoring activities in this industry.* Implementation of recommendations[14] that would require employers to report results of medical examinations and exposure monitoring to OSHA could complement laboratory-based surveillance and assist OSHA in identifying industries and employers who appear to be out of compliance with monitoring requirement.

Total	229,434	59,142	2.58

[a]Based on employer survey report.
[b]Based on industrial measurements from fed/OHSA or judgment of industrial hygienist.[9]
[c]Companies in this SIC without "radiator" in the name excluded.

Approximately 12 percent of potentially lead-exposed individuals are in construction jobs which are not covered by the Lead Standard.** In this segment, monitoring is extremely limited—for example, no plumbing employees were reported to have biological monitoring for lead, and less than 1 percent of those painting with lead-based paints worked in environmentally monitored positions. Yet reports indicate a serious continued potential for lead poisoning in the construction industry.[13]

Our findings suggest a need for new strategies for enforcement and enhanced compliance with the existing occupational lead standard, as well as a need for expansion of the standard to cover construction workers. Increased employer and worker education regarding lead and the lead standard are also warranted. Education and targeted compliance may be particularly important in small and non-unionized shops.

In conclusion, only a small proportion of the large number of potentially lead-exposed workers in California work in positions which have ever had industrial hygiene monitoring; an even smaller proportion participate in a routine biological monitoring program. Workers in small and non-unionized facilities are especially unlikely to participate in any type of monitoring program. The failure of employers to establish legally mandated environmental and biological monitoring programs severely limits the ability of laboratory-based surveillance programs to adequately fulfill critical functions of occupational disease or exposure surveillance. This, in turn, severely impedes our progress in the prevention and ultimate elimination of occupational lead poisoning.

TABLE 4—Estimated Percent of Lead-exposed Employees Receiving Routine Biological Monitoring by Highest Level of Potential Exposure Reported at Their Workplace and by Facility Size

Level of exposure	Number of employees at facility 1–19	20–99	100–499	>500	All facilities
High	0.52	9.90	48.99	15.90	16.34
Moderate	0	0	8.38	1.01	1.1€
Low	0	0	0.24	0.10	0.05
All facilities	0.06	0.55	11.27	4.09	2.58

**The construction industry is required to meet other OSHA standards limiting lead exposure to 200μg/m³, but is not required to provide air or blood monitoring.

Accelerated Nursing Program at JHU Quadruples Enrollment in 2nd Year

The shortage of nurses in the United States will be eased by former park rangers, Peace Corps volunteers, teachers, flight attendants, and even an ex-circus clown, according to word received from the Johns Hopkins Medical Institutions. Enrollment in an accelerated nursing program there has quadrupled during its second year.

The program, initiated last year in response to the nationwide need for high quality nurses, allows individuals who already hold a bachelor's degree in some other field to earn a bachelor's in nursing in just 15 months—nearly half the time it ordinarily takes to become a registered nurse.

The accelerated program was established to attract a new pool of bright students into the nursing profession by providing an intensified curriculum that responds to their academic and clinical needs. While 13 in the current class have just graduated from college, the majority of students are choosing nursing after working at a previous career, such as those listed above.

The current class of 60 future nurses at JHU includes 10 men. Students range in age from 20–51 years, come from 17 different states, and hold degrees from Stanford, Duke, Antioch, Smith, the University of Virginia and the University of Chicago, among other institutions. Ten members of the new class hold master's degrees.

More than one in every 10 budgeted positions for registered nurses in US hospitals is vacant at the present time, and as many as one in five budgeted nursing home positions is empty. It has been estimated that it would take about 130,000 full-time registered nurses to fill vacant positions in hospitals and nursing homes across the nation.

Field Comparison of Several Commercially Available Radon Detectors

R. William Field, MS, and Burton C. Kross, PhD

Abstract: To determine the accuracy and precision of commercially available radon detectors in a field setting, 15 detectors from six companies were exposed to radon and compared to a reference radon level. The detectors from companies that had already passed National Radon Measurement Proficiency Program testing had better precision and accuracy than those detectors awaiting proficiency testing. Charcoal adsorption detectors and diffusion barrier charcoal adsorption detectors performed very well, and the latter detectors displayed excellent time averaging ability. Alternatively, charcoal liquid scintillation detectors exhibited acceptable accuracy but poor precision, and bare alpha registration detectors showed both poor accuracy and precision. The mean radon level reported by the bare alpha registration detectors was 68 percent lower than the radon reference level. (*Am J Public Health* 1990; 80:926–930.)

Introduction

Radon provides the primary source of ionizing radiation exposure in man, imparting a greater effective dose equivalent to the average individual than other natural and man-made radiation sources combined.[1] Although radon has always existed in the environment, it did not become a major public health concern until 1984, when high radon levels were discovered in eastern Pennsylvania homes.[2] In 1986, the United States Environmental Protection Agency (EPA) estimated that up to 20,000 lung cancer deaths per year in the US may be due to exposure to radon.[3] The news coverage, public information campaigns, and reported health consequences that followed these discoveries initiated the cascade of public interest, awareness, and anxiety that surrounds radon today.

Public concern over radon in individual dwellings has resulted in a rise in the number of primary companies that provide radon measurement services to over 700 companies nationwide. Although the US does not have a national program to certify radon measurement companies, the National Radon Measurement Proficiency (RMP) Program within the Radon Division of the US EPA Office of Radiation Programs determines the accuracy of radon detectors on a voluntary basis and informs the public of these results upon request.[4] The majority of states have no ongoing quality assurance program for radon testing enterprises operating within their borders. Iowa has recently initiated a certification program to set minimum requirements for radon testing and analysis,[5] but will still rely on the federal government to actually test the radon measuring devices. In most cases, before Iowa certifies companies for radon testing, the State Department of Public Health requires that companies pass National RMP Program proficiency testing. Nevertheless, if companies enroll in the National RMP Program for the first time, then certification can be granted, pending review of their application and proficiency testing which allows some companies to market their radon detecting devices for up to a year prior to completion of proficiency testing.

After a company enrolls in the proficiency program, it must submit a specified number of detectors (e.g. five charcoal canisters) to the EPA for testing. These detectors are exposed in a calibration chamber to known levels of radon and radon decay products and returned to the company for analysis. The radon level in the chamber is not revealed to the company. A company is judged proficient if the mean of the absolute value of the relative measurement errors (MARE) of all exposed detectors for a particular method (activated charcoal adsorption, alpha track detection, etc.) is less than or equal to 0.250. In addition to the above proficiency testing, the EPA performs intermittent blind testing of commercially purchased detectors. A company that fails to pass either the announced or blind testing will not pass proficiency for that round. However, the company may participate in the next round of testing which occurs at intervals of up to a year or longer.

The majority of radon detectors purchased in the US are used for performing an initial radon screening measurement, which can quickly and inexpensively determine if elevated radon levels exist in a home. If screening is performed in adherence to EPA radon measurement protocols,[6,7] then this initial measurement will usually represent the maximum radon concentration to which the occupants of the home may be exposed. It is crucial that the initial screening measurement be accurate, because this result dictates whether additional testing is necessary.

The National RMP Program uses only a controlled calibration chamber to test radon-detecting devices, which may not reflect conditions in a dwelling. For example, the accuracy and precision of the radon measurement in a dwelling may be affected by temporal radon variations, changes in particulate (dust) concentration and size, air movement, humidity, temperature, and degree of radon progeny equilibrium, whereas in a calibration chamber the radon concentration and environmental parameters are highly controlled. Because of these potential differences, it is not known whether the accuracy measured in a calibration chamber can be extrapolated to the field.

This study determines the accuracy and precision of several commercially available radon detectors in a field setting. The accuracy and precision of detectors that have passed National RMP Program testing are compared to those that are awaiting proficiency testing.

Methods

The study site was a basement bedroom (see Appendix A) located in a ranch style home in southeastern Iowa. This house was selected based on the following criteria:

- Its observed radon concentration reflects the mean radon level of 10.5 pCi/L found in a recent screening

study of 600 Iowa homes.* Prior radon sampling at the experimental site had shown that the basement bedroom radon concentration averaged 11 pCi/L during the winter months.

- The air in the home was conditioned with a humidified central forced-air heating system which maintained the relative humidity and temperature at 38–47 percent and 20°C, respectively.
- None of the four occupants (two adults and two children) smoked.
- Closed house conditions as described by EPA protocols could be monitored.

Radon detectors from six companies were chosen for this study (Appendix B). Criteria for detector selection included: large sales volume in Iowa, state certification or pending state certification, and ease of availability to consumers. In addition, detectors from two other sources not readily available to shoppers were chosen based on either ability to produce a true integrated average radon measurement (in the case of the electret ion chamber from Rad Elec, Inc.) or, widespread use in radon screening (in the case of the EPA's charcoal adsorption canister).

Radon detectors from each company listed in Appendix B were purchased from various southeast Iowa commercial sources, including hardware stores, discount stores, pharmacies, grocery stores, and a heating supply company. Placement of the radon detectors was performed in accordance with EPA protocols for screening measurements.[6,7] All the detectors were placed a minimum of 10.2 cm away from other objects, including other radon detectors. Except for normal entering and exiting, all windows and exterior doors in the home were closed 12 hours prior to and during the testing period; fans and ventilation systems that bring in outside air or exhaust house air were not operated. An occupant activity log was maintained to document maintenance of closed house conditions.

*Kross BC, Vust LJ, Field RW: Factors associated with elevated radon levels in rural areas. Manuscript in preparation.

A femto-Tech continuous radon monitor (CRM) was positioned in the center of a 4 m^2 platform. The platform, located on a queen size bed, was 0.9 m above floor level. Radon detectors from all but one company were evenly distributed around the CRM. As per the accompanying instructions, the detectors from Air Check, Inc. were suspended from the ceiling approximately 30 cm above the other detectors.

The femto-Tech radon monitor was calibrated before the study period commenced against a femto-Tech "master" unit. The "master" unit was calibrated in the EG&G Mound Technologies, Inc. Radon Chamber which participated in the cross comparison network of US Department of Energy and US EPA radon chamber facilities. The accuracy of the femto-Tech CRM is estimated to be within 10 percent. The CRM provided hourly printouts of the radon concentrations in the room and was operating 24 hours prior to and during the entire seven day study period which initiated at 1100 hrs on March 18, 1989 and terminated at 1100 hrs on March 25, 1989.

The radon measurement periods and numbers of detectors exposed from each company are listed on Table 1. With the exception of the electret ion chambers from Rad Elec, Inc., these measurement periods were based on the optimal exposure duration, as indicated in the instructions that accompanied each detector. Five electret ion chambers were exposed for each of the three exposure periods in order to evaluate the homogeneity of the bedroom radon concentration. Although there were three different radon measurement initiation dates, all measurements were terminated at 1100 hrs on March 25, 1989. One detector from each company and three detectors from Rad Elec, Inc. were used as field control detectors which remained sealed and stored in a low radon environment during the course of the study. The controls were labeled in identical fashion to the exposed detectors to ensure identical processing and mailed back to the companies with the other detectors on March 28, 1989. The measurement results for each type of detector were compared to the reference values established for the various exposure periods by the CRM.

TABLE 1—Precision and Accuracy of Radon Detectors

Company	Number of Detectors	Exposure (days)	Radon Level Mean ± S.D. (pCi/L)	*Coefficient of Variation (%)	**Mare	Reference Radon Concentration Mean (pCi/L)
Rad Elec, Inc.	5	7	10.2 ± 0.4	3.9	0.045	10.6
American Radon Services	15	7	10.8 ± 0.8	7.5	0.057	10.6
Air Check, Inc.	15	7	11.4 ± 1.1	9.6	0.098	10.6
The Radon Project	15	7	10.5 ± 2.7	25.9	0.169	10.6
Rad Elec, Inc.	5	5	10.1 ± 1.2	11.8	0.091	10.6
Terradex	15	5	3.4 ± 1.7	50.6	0.679	10.6
Rad Elec, Inc.	5	2	9.6 ± 0.5	5.1	0.052	9.2
Ryan Nuclear Labs	15	2	11.0 ± 0.8	7.7	0.198	9.2
Key Technology	15	2	10.3 ± 0.8	7.5	0.136	9.2
EPA	15	2	11.6 ± 0.5	4.4	0.264	9.2

*The coefficient of variation was calculated using a standard deviation carried out to three decimal places.
**The mean of the absolute values of the relative errors (MARE) must be ≤ 0.250 to pass proficiency. Its calculation is shown below.

$$MARE = \frac{\sum_{i=1}^{n} \frac{|M_i - T_i|}{T_i}}{n}$$

n = number of detectors exposed
M_i = measured value for detector i
T_i = target value for detector i (reference value in this case)

Results

A plot of the hourly measurement results obtained from the CRM is shown in Figure 1. The radon level in the bedroom showed considerable variation, especially during the last two days of the study which was probably related to increased ventilation rates in the basement. The occupant activity log notes that the children living in the home frequently opened the basement door leading to the outside during the evening of March 23 and the afternoon of March 24, 1989.

The measurement results for each type of detector are listed in Table 1. The measurements for the individual detectors from each company were reduced to the mean, standard deviation, coefficient of variation and MARE (Table 1) as a measure of the detectors' accuracy and precision.

The relatively small standard deviations within the three groups of electret ion chambers exposed for each time period indicate a fairly homogeneous radon concentration in the measurement area.

The MARE for the seven-day exposure detectors were all within the National RMP Programs requirement of ≤ 0.250.[4] The precision for the seven-day exposure duration detectors was below the 10 percent coefficient of variation as per the radon measurement protocol guidelines published by the EPA,[6] except for the radon detectors from the Radon Project which had a coefficient of variation of 25.9 percent.

Terradex's five-day exposure duration bare alpha track registration devices (BARDs) yielded a MARE in excess of the EPA's accuracy guidelines (≤ 0.250 required for accuracy) and a coefficient of variation in excess of the EPA's BARD radon measurement protocol precision guidelines[7] (≤ 20 percent required for precision).

The two-day exposure duration detectors from Ryan Nuclear Labs and Key Technology were both within the EPA guidelines for accuracy[4] and precision.[6]

Figure 2 shows the distribution of individual test results for each company and their relationship to the radon reference level.

The reported radon level for the blanks submitted to the companies were all < 0.5 pCi/L.

Discussion

The radon detectors that have already passed the National RMP Program displayed reasonable accuracy and precision when compared to the reference radon level generated by the continuous radon monitor. The diffusion barrier charcoal adsorption (DBCA) detector from American Radon Services and Air Check, Inc. appeared to be the best over-the-counter integrators of radon, yielding accurate results and acceptable precision for the week-long exposure period.

The accuracy of the charcoal adsorption (CA) detectors from Key Technology, Ryan Nuclear Labs, and the EPA was not as good as that attained for the DBCA detectors mentioned above, although the MARE from Ryan Nuclear Labs and Key Technology detectors was within 0.250. The EPA's CA detector accuracy was just above a MARE of 0.250 at 0.264. All three companies reported higher radon levels than the radon reference value for the 48-hour exposure period. The results from these detectors seem to be weighted by

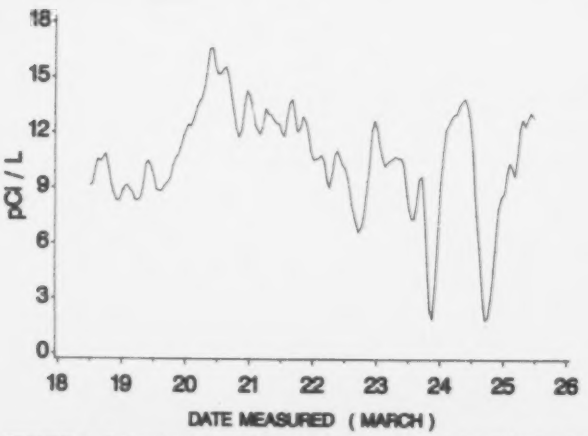

FIGURE 1—Interpolated Hourly Plot of the Radon Measurements Obtained from the Continuous Radon Monitor for the Period 1100 hrs March 18 to 1100 hrs March 25, 1989

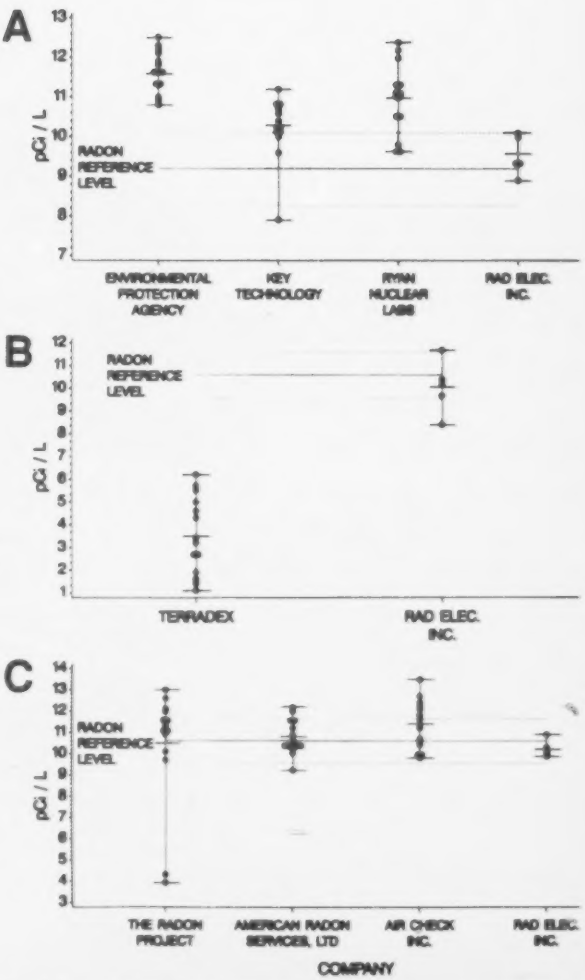

FIGURE 2—Comparison of the companies' individual detector results with the continuous radon monitor's reference value for the three exposure periods. Two (A), five (B), and seven (C) day exposure periods were initiated at 1100 hrs on March 18, March 20, and March 23, 1989, respectively. All three exposure periods ended on March 25, 1989 at 1100 hrs. The solid horizontal lines represent the radon reference values while the dotted horizontal lines indicate the confidence interval for the estimated accuracy of the continuous radon monitor. Each circle represents an individual radon detector measurement result. The means for the radon values reported by each company are indicated on the vertical range lines.

radon levels over the last 12 hours of the exposure period which averaged 11.9 pCi/L. These results are not unexpected, since the CA detectors do not integrate radon levels as well as the DBCA detectors. Despite the extreme fluctuations in radon levels, the two-day detectors performed reasonably well.

The detectors from the two companies awaiting proficiency testing did not perform well. Radon measurements using Terradex's BARD resulted in both poor accuracy and precision. Although the reference value was 10.6 pCi/L for the five-day exposure period, nine of the 15 detectors reported radon levels below 4 pCi/L (Figure 2B). The EPA recommends follow-up testing only if a screening radon test is above 4.0 pCi/L. If these detectors are representative of all Terradex's BARDs, then the majority of consumers with home radon levels and ambient conditions similar to the study site would theoretically receive radon measurement results below the EPA's action level of 4.0 pCi/L. This has significant public health implications, since these consumers would not perform follow-up testing or possible subsequent mitigation.

Several factors could influence BARD measurement variability, including ratio of radon daughters to radon in air, differences in the number of tracks used as background, locating objects less than 8 cm from the detector surface, variations in etching conditions and differences in readout.[7]

The results from the Radon Project's charcoal liquid scintillation (CLS) detectors underscore the importance of measuring precision. These detectors showed acceptable accuracy but poor precision (see Table 1). Since the National RMP Program has no requirements for precision the detectors would have passed proficiency, even though their coefficient of variation (25.9 percent) was over the EPA guidelines (≤10 percent) for precision. Thirteen detectors produced measured radon levels between 9.7 pCi/L and 13.0 pCi/L, but two detectors yielded results of 3.9 pCi/L and 4.3 pCi/L (see Figure 2C). The two lower results may be due to poor quality control of detector packaging. The two detectors that reported the highest (13.0 pCi/L) and the lowest radon level (3.9 pCi/L) both had loose vial caps upon initial examination. Loose caps compromise the detectors' seal, allowing both radon and water vapor to enter into the detector prior to actual deployment. Thus, the measured radon level could either be falsely elevated or lowered, depending on conditions that existed prior to detector use. For example, if the detectors with loose caps were stored in a high humidity environment, water molecules could reduce the number of radon adsorption sites on the charcoal, resulting in a lower measurement. On the other hand, if the detectors were stored in an area with high radon levels prior to deployment, a higher measurement could ensue.

In addition to the problems with the loose caps, six out of the 16 detectors purchased had diffusion barriers that had fallen out of the vial caps. The diffusion barrier is an integral part of this detector, allowing it to be marketed as a time-averaging device. It is unlikely that a consumer would search through the packaging material to replace a missing diffusion barrier. In this experiment all of the missing barriers were replaced into the vial caps. Securing the diffusion barrier to the cap would improve performance of this detector.

Finally, two of the 16 detector caps contained a second diffusion barrier which was not removed for our field experiment. These two detectors yielded results of 4.3 pCi/L and 11.4 pCi/L, compared to the reference CRM value of 10.6 pCi/L. Without further testing it is impossible to assess whether or not the extra vapor barrier affected the radon readings delivered by the detectors.

We offer the following recommendations to improve both the precision and accuracy of commercial radon detectors:

- States should require that companies pass proficiency testing by either the EPA or the state prior to selling their products. Interim or temporary certifications should not be granted while proficiency testing is being performed.
- The National RMP Program should require that detectors also pass a nominal precision criterion, as recommended in the Indoor Radon and Radon Decay Product Measurement Protocols[6,7] before passing proficiency testing.
- The National RMP Program should increase the rate at which it can test the detectors to accommodate the proliferating numbers of radon detecting companies.
- The National RMP Program should include occasional field testing of radon detectors.
- Radon chamber conditions should be diversified to better reflect the variety of actual home conditions.

APPENDIX A

Study Site in Southeastern Iowa

The bedroom has a poured concrete floor, and the south and east outside walls are constructed of concrete block. The east wall is about 1.5 m below grade while the south wall is even grade. The west and north walls are common to the rest of the basement. The floor covers an area of 14.4 m^2 and the ceiling height is 2.2 m, resulting in a total room volume of 31.7 m^3. There is a heating vent with an air flow rate of 0.12 m^3/min located 2 m above the floor on the northwest wall. Air flow rates in the study area averaged below 0.015 m/min. A well insulated window with blind is located in the south wall, and both windows and blind remained closed during the course of the study. However, the door to the room remained open so that the room could equilibrate with basement temperature, relative humidity, and radon concentrations.

Sites Listed for Nurse Scholars to Repay Educational Obligation

Recipients of scholarships for the undergraduate education of professional nurses are required upon graduation to serve at least two years in specified shortage sites. The Health Resources and Services Administration has announced a list of certain facilities where such recipients may repay their obligation. These include an Indian Health Service health center, a Native Hawaiian health center, a public hospital, a community or migrant health center, a nursing facility, a rural health clinic, or a health facility determined by DHHS to have a critical shortage of nurses. This announcement, which was published in the May 25 *Federal Register*, defines critical shortage facilities to include:

- All rural hospitals (classified by Medicare and Medicaid),
- All "disproportionate share" hospitals (those determined by Medicare and Medicaid as serving a disproportionate number of low income patients),
- Home health agencies approved for Medicare and Medicaid reimbursement,
- State and local health departments,
- Indian Health Service hospitals and other IHS facilities approved for Medicare and Medicaid reimbursement,
- Veterans hospitals, and
- Military health care facilities of the Department of Defense.

HRSA also announced that it is accepting FY 1991 grant applications for advanced nurse education. Applications must be submitted by October 1 to the Grants Management Officer, Bureau of Health Professions, 5600 Fishers Lane, Rm 8C-26, Rockville, MD 20857. Tel: (301) 443-6960.

Elevated Blood Lead in California Adults, 1987: Results of a Statewide Surveillance Program Based on Laboratory Reports

NEIL MAIZLISH, PHD, LINDA RUDOLPH, MD, PATRICE SUTTON, MPH, JEFFREY R. JONES, MPH, AND KENNETH W. KIZER, MD, MPH

Abstract: California medical laboratories that test for blood lead are required to report results exceeding 1.21 μmol/L (25 μg/dl). Between April and December 1987, the California Department of Health Services received 3,077 blood lead reports from 34 laboratories for 1,293 civilian, non-institutionalized adults.

Approximately 1 percent of all reports exceeded 3.87 μmol/L (80 μg/dl), 7 percent exceeded 2.42 μmol/L (50 μg/dl), and 21 percent exceeded 1.93 μmol/L (40 μg/dl). Individuals tested were overwhelmingly male (94 percent), disproportionately Hispanic surnamed (44 percent), and most often residents of Los Angeles County (81 percent).

Workers in lead smelting, battery manufacturing, and brass foundries accounted for nearly 80 percent of reports. Construction, radiator repair, pottery and ceramics manufacturing, and gun firing ranges accounted for the remainder. All adults with reports of ≥2.90 μmol/L who were contacted reported an occupational exposure. Approximately half were not in routine medical monitoring programs. Despite OSHA standards, elevated blood lead with the potential for serious acute and chronic lead poisoning in California adults remains a significant public health and major occupational health concern. (*Am J Public Health* 1990; 80:931–934.)

Introduction

Under a state law in effect since January 1, 1987, California medical laboratories performing tests for blood lead have been required to report personal identifiers and blood lead levels of individuals with tests exceeding 1.21 μmol/L (25 μg/dl), irrespective of age. The California Department of Health Services (CDHS) was charged with notifying laboratories, establishing a proficiency program for laboratories, designing report forms, and tabulating the reports. Over 95 percent of blood lead reports received from this program in 1987 were for persons greater than 16 years of age, and are the basis of this report.

Workplace exposures to lead are regulated under a standard issued in 1978 by the federal Occupational Safety and Health Administration.[1] The standard established an exposure limit of 50 $\mu g/m^3$ for airborne lead exposures for an 8-hour work day, and required employers to provide training, respiratory protection, work clothes changes, shower facilities, and a medical surveillance program, including annual physical examinations and periodic blood lead tests to eligible employees. Workers in agriculture and construction are currently excluded. The standard requires that workers with blood lead levels exceeding 1.93 μmol/L be re-tested bimonthly and those exceeding 2.90 μg/dl (or average 2.41 μmol/L on three previous tests) be immediately transferred and placed in jobs with low or no exposure.

This article describes initial results from a pilot program for surveillance of blood lead reports from medical laboratories and from follow-up of adults with reported blood lead levels of 2.90 μmol/L.

Methods

Patient identifiers, demographics, blood lead level, and other relevant information were reported by laboratories on specially designed forms. If the gender field of the registrant was blank, one was designated on the basis of first name of the registrant. An indicator of Hispanic surname was also designated. Industry of employment was based on an assignment of the Standard Industrial Classification (SIC)[2] code for reports that included an employer identifier. Employer name and address on the report form were matched to listings in the 1987 California Manufacturers Directory.[3] The SIC code for the primary business activity was then assigned to the report. Due to a paucity of complete data, occupation was not coded.

Follow-up of Elevated Blood Lead Reports

A working draft protocol for follow-up of reports was implemented for cases exceeding 2.90 μmol/L. Individuals and their physicians and employers were traced, and structured telephone interviews were administered to determine: the level of direct medical supervision, if any; work history and source of exposure, occupational and/or non-occupational; number of household contacts less than 7 years of age; number of co-workers exposed to lead; use of personal protective equipment and hygienic practices at work; and application of medical removal requirements of the federal OSHA lead standard.

An information packet was sent to the worker, his/her physicians, and employer.[4–6] Subsequent blood lead reports were tracked until levels fell below 1.93 μmol/L; workers were re-contacted if their subsequent blood lead levels abruptly increased.

Employers were informed of free industrial hygiene services available from the state OSHA Consultation Services, or encouraged to seek private consultants for technical consultation. Apparent egregious violations of the OSHA lead standard were channeled to appropriate enforcement agencies for follow-up. A recommendation to screen children and/or household contacts for elevated blood lead was forwarded to the state and local health officials when household contacts included children at risk of parental take-home exposures or non-occupational activities, or when an adult's exposure was non-occupational.

Laboratory Certification

A proficiency program was established by CDHS, and, according to its protocol, laboratories are certified as proficient if lead concentrations are reported within 15 percent of

target values for concentrations less than 1.93 μmol/L, or within .29 μmol/L of target values for concentrations greater than 1.93 μmol/L in 75 percent of at least nine reference samples.

Results

Blood Lead Distributions

Between April and December 1987, CDHS received 3,077 blood lead reports from 34 laboratories for 1,293 civilian, non-institutionalized adults, 16 years and older. Blood lead level was filled in on 3,024 report forms, and 2,643 reports were greater than 1.21 μmol/L (Table 1). Approximately 60 percent of individuals had only one test, 14 percent had two tests, 5 percent had three tests, and 22 percent had four or more tests in 1987.

Of reports greater than 1.21 μmol/L, approximately 1 percent (24) were equal or greater than 3.87 μmol/L, 7 percent (198) were equal or greater than 2.42 μmol/L, and 25 percent (649) were equal or greater than 1.93 μmol/L. Counting individuals once, but at their highest blood lead level in 1987, 355 individuals (31 percent) had a peak blood lead level of 1.93 μmol/L or greater; 124 (11 percent) peaked at 2.42 μmol/L or greater; 56 (5 percent) peaked at 2.90 μmol/L or greater; and 16 (1 percent) had peak levels at or above 3.87 μmol/L (Table 1).

Distribution by Age, Sex, Hispanic Surname, and Residence

The age distribution was that of a working population with 32 percent in their fourth decade (Table 2). Individuals were overwhelmingly male and disproportionately Hispanic surnamed. The blood lead distribution was similar in those with and without Hispanic surnames. Hispanics comprise approximately 24 percent of California's population. Of reports with known zip code, 81 percent were of residents of Los Angeles County (Table 2).

Distribution by Industry

Ninety-one employers were identifiable by name, and accounted for 2,521 (82 percent) reports. SIC codes were not obtainable for 1,109 (36 percent) of reports because the employer identifiers were blank or did not match entries in the California Manufacturer's Directory (Table 3). Based on the laboratory name (indicating that an employer-operated laboratory performed the blood lead analysis), three employers apparently accounted for 67 percent (2,070) of reports.

TABLE 1—Distribution of Blood Lead Reports at or Above 1.21 μmol/L, April–December 1987

Blood Lead Level	Total Reports[a]		Individuals at Peak Lead Level[b]	
μmol/L[c]	No.	%	No.	%
1.21–1.44	717	27	275	24
1.45–1.92	1277	48	508	45
1.93–2.41	451	17	231	20
2.42–2.89	98	4	68	6
2.90–3.37	52	2	26	2
3.38–3.86	24	.9	14	1
3.87–4.34	11	.4	5	.4
4.35–4.82	6	.2	6	.5
4.83–5.30	2	.1	2	.2
5.31+	5	.2	3	.3
Total	2643	100	1138	100

a) 382 reports less than 1.21 μmol/L (25 μg/dl) were received, but not included above.
b) Includes multiple reports on some individuals.
c) 1 μmol/L = 20.7 μg/dl; 10 μg/dl = .483 μmol/L.

TABLE 2—Demographic Characteristics of Individuals with a Blood Lead Report, April–December 1987

Item	No.	Percent
Age (years)[a]		
16–19	8	1
20–29	134	21
30–39	203	32
40–49	136	21
50–59	114	18
60+	45	7
Sex[b]		
Male	1059	94
Female	71	6
Surname[c]		
Non-Hispanic	687	56
Hispanic	547	44
County of Residence[d]		
Los Angeles	1092	81
Other	258	19

a) Excludes 653 reports not stating age.
b) Excludes 162 individuals for whom gender was not stated or determined.
c) Excludes 37 individuals for whom surname was not classified.
d) Excludes missing data (1457 reports) and 27 out-of-state reports.

Apparently, the reporting was done in the context of employer-based medical screening programs mandated by the OSHA lead standard. Three employers engaged in secondary lead smelting, 11 employers engaged in battery manufacture, and 12 brass, lead or copper foundries accounted for 1,656, or 55 percent of all reports. Construction, radiator repair, pottery and ceramics manufacturing, and gun firing ranges accounted for the remainder. Reports of construction workers in demolition and paint stripping represented 0.7 percent (23 of 3,077) of all reports, with 15 percent (15 of 100) of reports exceeding 2.90 μmol/L.

Follow-up of Persons with Elevated Blood Lead Levels

Of the 57 persons with blood lead levels exceeding 2.90 μmol/L, 33 (58 percent) were traced and completed telephone interviews; all persons reported occupational lead exposures. Sixteen reported that their blood lead test was part of an employer-sponsored medical monitoring program; 13 were symptomatic workers who sought medical care from a private physician. At least 10 persons had been hospitalized for treatment, including chelation. Many workers expressed deep reservations and fear of job discrimination when CDHS interviewers proposed pursuing follow-up activities with the employer (even without disclosing the name of the case).

Some individuals apparently covered by the OSHA lead standard had not been removed from their job, and some individuals who had been removed were working at other jobs within the same company at a lower pay rate in apparent violation of the OSHA lead standard. One worker alleged that employers colluded to prevent him from obtaining employment because of a history of elevated blood lead.

Because of worker concerns over potential employment discrimination, the protocol was modified and employer contact was generally limited to emergencies involving reports of blood lead exceeding 3.87 μmol/L. At levels between 2.90 and 3.87 μmol/L, follow-up with the employer was pursued if an employee did not express reservations about contact with the employer, or other workers at the worksite with elevated blood lead levels did not object to contact with the employer.

A number of physicians apparently charged with carrying out employer medical monitoring programs were unfa-

*Coding of the Standard Industrial Classification (SIC, 1972 Rev.) was based on matching the employer name on the lead report form to those listed in the 1987 California Manufacturer's Directory.

**Less than five reports were received in each of the SICs: inorganic pigment (2816), printing ink (2893), non-ferrous wire (3357), non-ferrous foundry (3360), fabricated metals (3499), special tool manufacturing (3544), local transportation (4111), ship manufacturing and repair (3731), and assay laboratories (7397). Table includes all reports received, including some reports below 1.21 μmol/L.

†Missing data: SIC could not be assigned either because employer identifiers were missing on report, or did not match to entries in the California Manufacturer's Directory (1987).

miliar with the OSHA lead standard. A few physicians were totally unfamiliar with normal limits of blood lead in adults.

Discussion

Before implications of these data can be discussed and conclusions drawn, limitations and potential biases of the data will be discussed. The most important potential bias is the undercounting of lead-exposed individuals with elevated blood lead levels who do not have their blood tested periodically for lead. This prevents the full estimation of the prevalence of elevated blood lead among California adults. Undercounting that differentially affects subgroups also can introduce distortions.

Certain geographic areas and certain industries were probably underrepresented. For example, data from the California Employment Development Department (CEDD) indicated that there were approximately 14,500 employees in 2,790 radiator repair establishments in 1985. However, only three employers, accounting for 15 reports were found in the lead registry in 1987. Similarly, in lead battery manufacturing, where there also is a high probability of direct lead exposure, 11 employers accounting for 496 reports were found in the lead registry, although CEDD data indicated that there were 33 employers with 2,500 workers in June 1985.

The lack of employer-based medical monitoring programs for lead-exposed workers appears to be a significant problem. A recent survey based on a probability sample of California employers indicated that only 2 percent of workers with direct exposures to lead were enrolled in an employer-sponsored, medical monitoring program.[7] Some industries, such as construction, are exempted from the lead standard and medical monitoring requirements.

Underreporting may also result when an out-of-state laboratory analyzed the blood lead of California workers, or an in-state laboratory failed to report. While some out-of-state laboratories did report on a voluntary basis, out-of-state laboratories appear to analyze 47 percent of blood tests of California employers.[7] Since virtually all California laboratories performing lead tests were contacted by CDHS, and failure to report can result in a fine, it is probable that few, if any, California laboratories did not report.

Lack of complete information on basic demographic data such as age, residence, and occupation occurred in a significant proportion of reports. This limits an accurate profile of subgroups where risk may be concentrated and surveillance needs to be expanded.

The timeliness of reporting is another concern for timely case follow-up, particularly for persons with highly elevated blood lead levels. On average, reports were received by CDHS 22 days after blood lead specimens were analyzed by the laboratory. Only 9 percent of report forms were received by CDHS within 72 hours of analysis as required by the reporting requirement. While emergency response was not initially anticipated, follow-up of highly elevated lead cases revealed situations in which imminent hazards had not been abated, and recommendations had or might have had a positive impact.

These data from California's newly implemented blood lead surveillance program indicate the need for intensified lead poisoning surveillance, education, and enforcement in California. Workers, employers, physicians and other health care personnel, laboratories, and government agencies would benefit from expanded training and education focused on lead-related health problems.

The wider implications of this finding is that without an immediate and concentrated effort to reduce occupational lead exposures, it is unlikely that the Public Health Service goal[8] of eliminating lead poisoning by 1990 will be met in California. These data also indicate that current regulations for construction workers exposed to lead do not prevent lead poisoning, and revisions need to be seriously considered. Further, these data indicate the need for occupational health and safety agencies to more vigorously and expeditiously enforce the lead standard.

Johnson Foundation Announces $3 Million R&D Program to Improve Patient Care

An increasing amount of complex patient care in the United States is being delivered in nursing homes, in ambulatory care clinics, and at home. Yet, the tools and techniques needed to assure that patients receive high quality care in these settings have not yet been fully developed. In an effort to improve services for long-term and ambulatory care patients, the Robert Wood Johnson Foundation of Princeton, NJ, will make available up to $3 million to stimulate and support research and demonstration projects that will identify new and practical mechanisms to assure the delivery of high quality patient care.

The types of projects that will be considered for funding under the foundation's three-year initiative are: research and development of tools that assess the quality of patient care and identify patient care problems and exemplary practices: demonstrations of new approaches to improving quality of care; and evaluations of policies and of systems designed to improve quality of care.

Projects considered for funding may: develop new ways to identify problems in the quality of patient care in specific settings; test existing tools; design and demonstrate institution-wide systems to locate and solve patient care problems; or evaluate existing improvement systems or policies. Projects involving clinical interventions, treatment or drug therapies will *not* be considered under this initiative.

Institutions wishing to apply for funds are asked to submit five copies of a letter of intent of no more than four double-spaced pages, addressed to: Phyllis Kane, Program Assistant, Robert Wood Johnson Foundation, P.O. Box 2316, Route 1 and College Road East, Princeton, NJ, 08543-2316. Based on a review of the letter, the foundation may request a full proposal at a later date.

Technical assistance for the program will be provided by Jack D. McCue, MD, of Baystate Medical Center in Springfield, Mass., and Andrew Kramer, MD, of the University of Colorado Health Sciences Center in Denver.

Recent Time Trends in Uterine Cancer

VICTORIA PERSKY, MD, FAITH DAVIS, PHD, RICHARD BARRETT, PHD, ELIZABETH RUBY, MS, CAROLE SAILER, BA, AND PAUL LEVY, SCD

Abstract: Recent trends in corpus uterine cancer incidence rates were explored using 1979–86 data from the Surveillance and End Results Program (SEER); recent trends in hospitalizations for corpus uterine cancer were explored using 1979–86 data from National Hospital Discharge Surveys (NHDS); and recent trends in exogenous hormone use were delineated using data from the 1980, 1981, and 1985 National Ambulatory Medical Care Surveys (NAMCS). Uterine cancer incidence rates using SEER data have continued to decline since 1979. An acceleration in the decline since 1983–84 is suggested in all women and in women with intact uteri ages 45–64. Hospitalizations for uterine cancer have also declined since 1979, with a marked acceleration in the decline since 1983–84 for all women and for women ages 40–79 has increased 22 percent and use of unopposed exogenous estrogens in women of similar age has increased 7 percent, while use of exogenous progesterones have shown much more substantial increases of approximately 700 percent. Possible relationships between trends in exogenous hormone use and incidence rates of corpus uterine cancer are discussed. (*Am J Public Health* 1990;80:935-939.)

Introduction

Incidence rates of cancer of the corpus uterus showed striking increases in the early 1970s following increases in use of postmenopausal estrogens.[1-3] Subsequently, incidence rates of corpus uterine cancer declined in the late 1970s following declines in use of estrogens.[1] Since 1980, there has been an increase in use of progestins cycled with estrogens in an effort to combat the carcinogenic effect of unopposed estrogens while allowing for a protective effect of estrogens on osteoporosis.[4] The effect of exogenous progesterones on trends in uterine cancer, however, has not been documented. The purpose of the current paper is to delineate more recent time trends in corpus uterine cancer incidence and hospitalization rates in the 1980s in relation to the increasing use of exogenous progestins.

Methods

Age-specific and age-adjusted cancer incidence rates were obtained for the years 1979 through 1986 from the Surveillance Epidemiology and End Results (SEER) Program of the National Cancer Institute. The SEER Program identifies newly diagnosed cancer cases at 11 locations, including nine in the mainland United States plus Hawaii and Puerto Rico. These data, collected since 1973–75, cover approximately 10 percent of the total population of the United States and are considered fairly representative of the US population with respect to age, although Blacks and rural populations are underrepresented. Details of the SEER data collection have been published elsewhere.[5] In the current report, corpus uterine cancer includes ICD-O topography codes 180.0-182.8.[6]

Corpus uterine cancer hospitalization rates between 1979 and 1986 were obtained from the National Hospital Discharge Surveys (NHDS) of the National Center for Health Statistics.[7] Although hospitalization rates are not an exact measure of incidence rates, analyses of trends in the NHDS are presented as a second source of data which, in part, reflect trends in cancer incidence. The NHDS encompasses a representative sample of patients discharged from short stay hospitals, exclusive of federal hospitals, in the 50 states and the District of Columbia. No distinction in NHDS is made between initial admissions and readmissions for corpus uterine cancer. Population estimates are determined by multiplying individual data by sampling weights. In the current report, corpus uterine cancer includes ICD-9 CM code 182.0–182.8.[8]

Hormone use was determined from the National Ambulatory Medical Care Survey (NAMCS) conducted in 1980, 1981, and 1985 with a multistage probability sample of patient visits to office-based physicians in the United States. Physicians were asked to record up to five drugs prescribed at the visit for a random sample of office visits occurring during a randomly selected week during the year.[9,10] Physicians were asked to include both prescription and non-prescription drugs. All medicines containing either estrogens or progesterones were enumerated by year. Birth control pills were not include[d] in these analyses. Medications containing both estrogen and testosterone, however, were included. In 1980, 1981 and 1985, they accounted for an estimated 3.2 percent, 1.0 percent, and 0 percent, respectively, of all estrogens prescribed by physicians for women ages 40–79 in those years. Population estimates were determined by multiplying individual data by sampling weights.

Information on age-specific populations at risk was abstracted from census data.[11] Cancer rates from SEER and NHDS were then calculated by dividing the age-specific estimated numbers by the age-specific populations. In addition, the populations at risk (i.e., women with intact uteri) were establishing by estimating the cumulative age-specific proportions of women who had hysterectomies from hospital discharge data and excluding them from the denominator.[12] Cohort interpolation techniques were used to estimate the proportion of women with intact uteri at single years of age between 1979 and 1986; these figures were then combined to produce five-year rates. Age-adjusted uterine cancer rates from SEER were calculated both by standardization to the 1970 population with uterine cancer not otherwise specified (NOS) included in the data for purposes of comparability to other SEER publications, and by direct standardization to the 1980 population ages 40–79 without NOS included for purposes of comparability with NHDS data. Age-adjusted hospital admissions for uterine cancer rates from NHDS were

calculated for ages 40–79 by direct standardization to the 1980 population. Age-specific and age-standardized rates were averaged over two-year intervals, to increase the stability of the estimates.

For the NAMCS and NHDS data, standard errors of the age-specific rates were obtained by use of charts, tables, or formulas developed by the National Center for Health Statistics for these surveys. By appropriate algebraic manipulation of these age-specific standard errors, 95 percent confidence intervals were obtained for differences between successive two-year averages of the age-adjusted rates. For the SEER data, the variance among the eight age-adjusted single year rates was computed and this estimated variance was used to obtain 95 percent confidence intervals for differences between successive two-year averages of age-adjusted rates. Also, for the SEER data, linear regression methods were used to estimate the magnitude and statistical significance of the linear component of the time trend in the age-adjusted incidence rates.

Results

For the SEER data, there was a consistent decline each year in the age-adjusted incidence rate from 1979 through 1986 ($p \leq 0.0001$). The average yearly decline in these rates from 1983 to 1986 ($0.77/10^5$) was higher than the decline from 1979 to 1982 ($0.43/10^5$). However, the differences between the two average declines was not statistically significant. As seen in Table 1, age-adjusted uterine cancer incidence rates in SEER declined approximately 1 percent per year between 1979–80 and 1983–84 and 2–3 percent per year between 1983–84 and 1985–86 for all women and for women with intact uteri. Confidence intervals for the declines in age-adjusted rates, however, for each time period included zero. Most of the decrease in uterine cancer rates occurred in the age groups 45–64, with 14–27 percent declines at those ages and with no particular trends apparent in the older and younger age groups (Figure 1).

As seen in Table 2, admissions for uterine cancer in the NHDS declined approximately 1–2 percent per year between the years 1979–80 and 1983–84 and 6 percent per year between 1983–84 and 1985–86. Confidence intervals for the declines in rates between 1983–84 and 1985–86, but not from 1979–80 to 1983–84, excluded zero. Overall trends were similar among different age groups (Figure 2).

As shown in Table 3, between 1980 and 1985 the total number of prescriptions for estrogens increased 22 percent from 11.3 to 13.8 per 100 persons ages 40–79. When women receiving both estrogen and progesterone were subtracted from the estimate, the prescriptions for unopposed estrogen use increased only 7 percent. Confidence intervals for both these increases included zero. During the same time period, however, total progesterone prescriptions increased from 0.6 to 4.9 per 100 persons (694%) and prescriptions for both estrogens and progesterones increased from 0.2 to 1.9 per 100 persons age 40–79 (946%). Confidence intervals for the increases in progesterone use excluded zero.

Discussion

The overall decline in uterine cancer rates since the mid-1970s[1–3] has been attributed primarily to a decrease in the use of unopposed estrogens. This paper documents the continuation of this trend from two different data sources and also suggests that since 1983–84 there may have been an acceleration in this decline in uterine cancer concomitant with little change, or even a slight increase, in unopposed estrogen use. Data from SEER, but not NHDS, suggest that the declines in uterine cancer rates may be localized to age groups between 45–64 years. Exogenous hormones are

thought to act at the promotional stage of uterine corpus carcinogenesis and to act within a short period of time: in the 1970s, trends in cancer rates followed trends in hormone use by only a few years[1] and case-control studies[13] estimate latent periods of only three to six years. Thus it is possible that the decline since 1979 partly reflects a very recent increase in use of postmenopausal progestins. A protective effect of progestins is consistent with lower risks of uterine cancer observed in women on birth control pills containing both estrogens and progesterones,[14–16] and with two recent studies in which post-menopausal women using estrogen-progesterone combinations were at somewhat lower risk of uterine cancer (OR = 0.6, CI = 0.2–1.4) and (OR = 0.9, CI = 0.4–2.0) than women not using hormones.[17–18] Previous studies have also noted that adenomatous hyperplasia, thought to be a precursor to endometrial cancer, is reversed by the addition of progesterone.[19] Similarly, estrogen receptor activity is increased by estrogens and decreased by progesterones, lending biologic plausibility to a protective action of progesterone on estrogen-induced cancer.[20]

Another possible explanation for the declines in uterine cancer rates since 1979 is a protective effect of birth control pills on cancer development, manifesting itself 10–20 years after exposure to contraceptives. Women currently ages 45–64 were ages 20–40 when oral contraceptives were first introduced. Older women were never exposed to oral contraceptives and were unlikely to have been exposed to postmenopausal progestins, which have been used only since 1970 and are used infrequently for women over age 65 years. In the current study, only 3–5 percent of progestins being prescribed for women in the years 1980, 1981, and 1985 were prescribed for women over 65 years of age.

Hospital discharge data cannot accurately measure uterine cancer incidence rates because hospitalizations, rather than people, are enumerated, and the same person hospitalized repeatedly for the same illness may be counted more than once. Rates of hospitalization for cancer in NHDS are higher than cancer incidence rates in SEER.[21] In the current study we found that hospitalization rates for uterine cancer based on NHDS were approximately twice the incidence rates for uterine cancer in SEER. Although much of the acceleration in the declines in hospitalizations seen since 1983–84 might be attributed to overall changes in hospitalizations secondary to the introduction of DRGs (diagnosis-

*95% confidence intervals for change in rate 1980–85.

related groups) preferentially affecting the elderly, the accelerations in the overall declines in incidence rates for corpus uterine cancer in SEER suggest that there may have been alterations in trends in incidence rates as well.

The use of physician office visit prescriptions to estimate hormone use is subject to several potential errors. Although total use of progesterone can be approximated, use of progesterone simultaneously with estrogen cannot be precisely measured, since the NAMCS measures prescriptions at an individual visit, rather than total prescriptions. In addition, although every effort was made to eliminate birth control pills from the analysis, it is possible that some of the younger women may have been using birth control pills, rather than estrogen and progesterone, as noted. The restriction of the analyses to women ages 40–79 should minimize this error.

The number of drug prescriptions may well be underestimated, since physicians were limited to a total of five drugs prescribed at each visit. A recent study using data from the National Disease and Therapeutic Index (NDTI) reported between 15 and 43 total oral estrogen mentions per 100 women ages 45–64 in 1985.[4] They also noted a substantial increase in the percent of women prescribed both estrogens and progesterone. Use of both hormones account for 4 percent of all estrogen mentions in 1979 as compared to 28 percent in 1986. Unlike the NAMCS in the current study, the NDTI includes outpatient clinics, prescriptions written in hospitals, and telephone prescriptions. Since ascertainment of drug use in the NHDS, however, was similar in each year of the study, systematic underestimates of exogenous hormone use should not affect time trends.

A detailed breakdown of specific estrogens used also revealed that a small percentage of women in 1980 and 1981 ingested hormones containing both estrogens and testosterone. A total of 3.2 percent of women using estrogens in 1980, 1.0 percent of women using estrogens in 1981, and 0 percent using estrogens in 1985 used medication also containing testosterone. These results are consistent with those of Hemminki, *et al*,[4] who also noted that injected androgen/estrogen preparations decreased from 7 percent in 1974 to 3 percent in 1986. We were not able to find any previous human studies which examined the effect of exogenous testosterone on endometrial hyperplasia. Studies in rabbits[22] and in endometrial adenocarcinoma in vitro cell lines,[23] however, indicate that testosterone has no effect on the development of hyperplasia or on tumor cell growth. Since only a small number of women in 1980 and 1981 were using testosterone, they were retained in the analysis. Finally, the numbers of women using progesterone in specific age strata were small, precluding reports of age-specific rates. Despite the problems in estimating estrogen and progesterone use, consistency with other data and the magnitude of the increase between 1980 and 1985 support the possibility that the increase in use of progestins may be contributing to an acceleration in the decline in uterine cancer since 1984.

ACKNOWLEDGMENTS

The authors are deeply grateful to Hugo Koch, Health and Survey Statistician with the Division of Health Care Utilization, and to Lynn Ries, from Cancer Statistics Branch of the Surveillance and Epidemiology End Results (SEER), Division of Cancer Prevention and Control, National Cancer Institute for their patient help in analyzing the data from the National Ambulatory Care Survey and SEER. The authors also wish to express their appreciation of the personnel at the Hospital Care Statistics Branch of the Division of Health Care Statistics at the National Center of Health Statistics for their consultation in analyzing the data from the Hospital Discharge Survey. Our thanks also to Dr. John Lurain and Dr. Bill Haenszel for their insightful comments.

Office of Minority Health Resource Center: A Nationwide Service

A nationwide service of the Office of Minority Health (OMH) within the federal government is the OMH Resource Center, a comprehensive information and referral service designed to assist health professionals in locating hard-to-find information. There is no charge for the service. The computerized database contains a directory of current resources, information and other materials on health issues relevant to Asians/Pacific Islanders, Blacks, Hispanics, and Native Americans in the United States.

The Database—Access to the database can be activated by calling OMH-RC where a knowledgeable information specialist can conduct searches of the database while you are on the telephone. The Resource Center database is organized into three types of reference information: a) organizations providing minority health-related services, community-based programs, and federally funded projects; b) information and materials by ethnic group, priority disease, or geographic area; and c) volunteer technical assistance experts.

Organizations—The database includes organizations prominent in minority health, such as coalition groups, community-based organizations, reference centers, national voluntary health-related groups; government and private agencies; disease support groups; clinical services; foundations; social service organizations; educational organizations, university research centers, etc.

Materials—The materials collection includes references on published and unpublished materials; federal reports; landmark studies; statistical reports; sources of foreign language materials; pamphlets; handbooks; training manuals; curricula; bibliographies; select listings by racial/ethnic groups; project reports; monographs; audiovisuals, videotapes, and audiocassettes; etc.

Technical Assistance—Technicals assistance is available through a unique service called the Resource Persons Network (RPN), a cadre of 2,000 health experts who have volunteered to offer their technical expertise to community and health organizations. To reach these individuals, you need only call the Resource Center, where an information specialist will assist you in locating potential contacts. The Resource Center functions solely as a a facilitator in this type of technical assistance.

Publications—The Resource Center produces and disseminates publications highlighting the minority health disparity issue, and is the distribution point for select free publications on minority health issues from federal agencies. Single copies are provided to individual requestors; bulk copies are handled as special orders by writing the OMH-RC Information Services Coordinator and specifying the number of copies desired and their intended use. These requests are handled by a separate bulk distribution center.

For further information about the Resource Center, contact: Kym Collins-Lee, Office of Minority Health Resource Center (OMH-RC), P.O. Box 37337, Washington DC 20013-7227. Tel: 1-800/444/6472.

Comments or inquiries for the Office of Minority Health should be directed to Annette M. Nieves, OMH, Room 118-F, HHH Building, 200 Independence Avenue, SW, Washington, DC 20201. Tel: 202/245-0020.

Cancer Mortality in Native Americans in North Carolina

RONNIE D. HORNER, PHD

Abstract: This paper describes age-adjusted mortality from malignant neoplasms for Native Americans in North Carolina for 1968–72 and 1978–82. Sex-specific standardized mortality ratios were calculated from death certificate data, using the cancer mortality experience of White North Carolinians to obtain the number of expected deaths. For most categories and specific sites of cancer, mortality was at or below the expected level, but higher than expected mortality was found for genitourinary cancers in males (SMR = 1.62, 95% CI = 1.15, 2.21) for the 1978–82 period; within this category, there was a higher than expected level of mortality from prostate cancer (SMR = 2.00; 95% CI = 1.36, 2.83) and cancer of the penis and other male genital organs (SMR = 9.09; 95% CI = 1.10, 32.84). Female Native Americans had an elevated mortality from cervical cancer (SMR = 2.27, 95% CI = 1.09, 4.17) for the 1968–72 period only. (*Am J Public Health* 1990; 80:940–944.)

Introduction

The epidemiology of cancer in Native American tribes in the eastern United States is not well described. Studies of the Seneca Nation in New York State found lower than expected mortality from cancers of all sites for males and females of this tribe.[1,2] In comparison to White residents of New York State (exclusive of New York City), Seneca women had lower mortality from cancers of the pancreas and breast, but higher mortality from cervical cancer; Seneca men had site-specific cancer mortality at or below the expected level.[1]

Native Americans nationally and in the Southwest show a lower than expected overall cancer mortality and incidence.[3,4] Alaskan Native Americans experience a level of mortality and incidence from all cancers which is similar to White Americans.[5–9] For specific sites, elevated mortality (and incidence) is found for cancer of the gallbladder (particularly for females),[3,7,10–13] esophagus and nasopharynx (for Alaskan Native Americans),[5,6,8,14,15] stomach,[16,17] cervix,[3,5,8,18,19] and multiple myeloma (in males).[20] Significantly lower mortality (and incidence) is found for lung cancer,[3,5,7,16,21] cancer of the female breast,[3,6,7,8,16] melanomas,[3,6] lymphomas and leukemias,[20] pancreatic cancer,[3,16] colon cancer,[3] and cancer of the prostate gland (particularly for Eskimos and Aleuts).[3,5–8] Alaskan Native Americans have an increasing incidence of lung cancer for both sexes; for females, esophageal and cervical cancers are decreasing.[6,7,9]

This report describes cancer mortality in Native Americans in North Carolina for the 1968–72 and 1978–82 periods, to gain insights into possible changes over time.

Methods

Native Americans in North Carolina are from several tribes, including the Cherokee, Coharie, Eno-Occan-Eechee, Haliwa-Saponi, Lumbee, Meherrin, Tuscardra, and Waccamaw-Sioun. The Cherokee in western North Carolina and the Lumbee in the eastern region of the State are the largest tribes. There has been considerable interbreeding between Native Americans, Whites and, to a lesser extent, Blacks in the region.[22–25] As a consequence, there are few "full-blooded" Native Americans in any of the tribes in the State. Moreover, cancer mortality data by tribe are not available.

Population data for this study came from the 1970 and 1980 US census reports for North Carolina.[26,27] Sixteen age categories were used: <5 years old, 5–9, 10–14, . . ., 70–74, and 75+ years of age. The distribution of Native Americans by sex but not age was available for 1970, so the sex-specific age distributions of Native Americans for 1980 were used to estimate the 1970 age distributions.

Cancer mortality data were obtained from the detailed mortality data tapes of the North Carolina State Center for Health Statistics using the underlying cause of death for North Carolina residents. Probably some Native Americans were classified as White. (The magnitude of the racial misclassification bias is currently under investigation: Personal communication from Dr. Tim E. Aldrich, director of the Central Cancer Registry of North Carolina.)

The mortality data were classified according to the broad categories of malignant neoplasms found in the International Classification of Diseases (ICD) and by specific sites within these categories.

The use of broad categories was necessary because the data for specific cancer sites for Native Americans in North Carolina were sparse. The use of broad categories also reduced the effect of changes in the classification of cancers; ICD-8 and ICD-9, though, are essentially identical for malignant neoplasms at the three-digit code level.

Specific sites identified by previous studies as being above or below the expected level were also given attention.

The standardized mortality ratio (SMR) was calculated using the 1980 age- and sex-specific cancer mortality rates of White residents to obtain the expected number of deaths. Although SMRs between different areas (times) usually should not be compared because of different standards, the identical age distribution in the Native American population in 1970 and 1980 (for the reason described) and the use of the same set of rates permit comparisons between time periods.[28] In essence, the only difference between the 1970 and 1980 SMRs are the cancer mortality rates for Native Americans which are reflected in the observed number of deaths. Cancer deaths were assumed to follow a Poisson distribution. The 95% confidence intervals for the sex-specific SMRs were calculated according to the approach described by Kahn and Sempos.[29]

Results

The proportion of observed cancer deaths by category among Native American and White residents of North Carolina in 1968–72 and 1978–82 is shown in Table 1. For

TABLE 1—Percentage Distribution of Deaths from Malignant Neoplasms, Native Americans and White Residents of North Carolina, 1968–72 and 1978–82, by Sex and Category*

Category of Malignancy (ICD Code)	Native Americans		Whites	
	1968–72	1978–82	1968–72	1978–82
Males	(n = 76)	(n = 150)	(n = 13,747)	(n = 20,317)
Lip, Oral Cavity, and Pharynx (140–149)	1.3	2.7	3.3	2.3
Digestive Organs and Peritoneum (150–159)	27.6	19.3	22.5	21.5
Respiratory and Intrathoracic Organs (160–165)	19.7	30.0	32.8	38.2
Bone, Connective Tissue, Skin, and Breast (170–175)	1.3	0.7	3.7	3.2
Genitourinary Organs (179–189)	23.7	26.0	14.8	14.4
Lymphatic and Hematopoietic Tissue (200–208)	14.5	11.3	11.1	9.2
Other and Unspecified Sites (190–199)	11.8	10.0	11.8	11.3
Females	(n = 44)	(n = 89)	(n = 11,268)	(n = 16,285)
Lip, Oral Cavity, and Pharynx (140–149)	2.3	3.4	2.0	1.6
Digestive Organs and Peritoneum (150–159)	18.2	27.0	25.5	25.2
Respiratory and Intrathoracic Organs (160–165)	2.3	3.4	7.3	13.8
Bone, Connective Tissue, Skin, and Breast (170–175)	18.2	19.1	22.7	22.1
Genitourinary Organs (179–189)	36.4	19.1	18.4	14.7
Lymphatic and Hematopoietic Tissue (200–208)	9.1	13.5	10.8	10.2
Other and Unspecified Sites (190–199)	13.6	14.6	13.2	12.4

*Percentages may not sum to 100% due to rounding.

White residents of both sexes, the proportion of cancer deaths within each category is fairly stable between the two periods. Among male Native Americans, deaths from cancer of the digestive organs and peritoneum decreased, but deaths from cancers of the respiratory and intrathoracic organs increased. For female Native Americans, deaths from cancers of the digestive organs and the peritoneum increased, but genitourinary cancer deaths decreased. None of the differences between time periods were statistically significant.

As Table 2 shows, Native Americans experienced a generally lower or equal level of mortality from the various cancers to that expected based on the experience of White North Carolinians. The only clearly elevated SMR is for genitourinary neoplasms in male Native Americans for the 1978–82 period (SMR = 1.62, 95% CI = 1.15, 2.21); the SMR for this category is also elevated for 1968–72.

The SMRs in Table 2 suggest that changes in cancer mortality for Native Americans may have occurred between 1968–72 and 1978–82. There is an increase in the number of cancer deaths for Native American females from significantly below to near the expected levels for digestive organ and peritoneum cancers. A similar change occurs for respiratory and intrathoracic cancer mortality for male Native Americans. Also as noted previously, deaths from genitourinary cancers increased from a level similar to the expected number to a higher number for male Native Americans. Both sexes may also be experiencing an increase in cancers of the lip, oral cavity, and pharynx.

Table 3 shows the SMRs associated with specific cancer sites which have been identified as having significantly above or below expected mortality for Native Americans. The SMRs for each three-digit site are available on request to the author. Most deaths from cancer at the various anatomic sites are at levels similar to that found among White residents of North Carolina. Deaths from cancer of the breast and colon are lower than expected in both time periods for females. Mortality from cancer of the cervix uteri was more than twice that of Whites in 1968–72 and in 1978–82. A slight increase in mortality from prostatic cancer is indicated; and rates are elevated in both periods. Mortality from cancer of the penis and other male genital organs (ICD 187) is also significantly elevated in both periods.

Discussion

The Native Americans in this report represent several tribes which have bred extensively with other racial groups, and yet their cancer mortality experience generally follows that of Native Americans elsewhere in the nation, with lower than expected mortality from cancers of all sites, respiratory and intrathoracic cancers, and cancers of the female breast, but a higher than expected mortality for cancer of the cervix uteri. The higher mortality from prostate cancer seen in this study was also found for Alaskan Indians.[3,5,6,8] A unique finding of this study is the elevated mortality from cancer of the penis and other male genital organs (ICD 187). Unlike Alaskan Native Americans, no nasopharynx cancers were reported in either study period. Nor was there a higher than expected mortality from cancers of the gallbladder and stomach which are common in tribes of the Southwest.

Clearly elevated mortality in North Carolinian Native Americans was found only for cancers of the prostate, male

TABLE 2—Standardized Mortality Ratios (95% CI) for Malignant Neoplasms, Native American Residents of North Carolina, 1968–72 and 1978–82, by Sex and Category

Category of Malignancy (ICD Code)	Males		Females	
	1968–72 (95% CI)	1978–82 (95% CI)	1968–72 (95% CI)	1978–82 (95% CI)

genitalia, and the cervix. Prostatic and penile cancers are more prevalent in Blacks than either Whites or Native Americans generally.[30,31] However, the racial mixing in Native Americans of North Carolina is unlikely to account for their unexpectedly higher mortality from these cancers because the Black contribution to the genetic pool of most tribes of the Carolinas is indicated to be minimal.[22–25] Diet may be involved in cancer of the prostate. Although controversial, there is epidemiologic evidence of a positive association between prostatic cancer and a diet high in fats and vitamin A, particularly in older males.[32–35] However, an inverse association between the level of consumption of green and yellow vegetables (and hence vitamin A) and prostatic cancer is found for Japanese males.[36] Dietary information on North Carolinian Native Americans is not available. The elevated mortality from cervical cancer may indicate a low level of cervical cancer screening among Native American females in North Carolina. An inverse association between extent of cervical cancer screening in populations and mortality from cancer of the cervix is reported for Native Americans elsewhere.[18,19]

There is indication that the cancer mortality experience of North Carolinian Native Americans may be worsening, which would suggest that the lower than expected cancer mortality for Native Americans is more strongly related to environmental factors than to genetics. Although the number of cases is too few for definitive conclusions, an increase in mortality may be occurring from: cancer of the lip, oral cavity, and pharynx for both sexes; cancers of the respiratory and intrathoracic organs, and genitourinary organs for males; and cancers of the digestive organs and peritoneum for females. For specific sites, an increase in mortality may be occurring for cancer of the prostate and the trachea, bronchus, and lung for males. It has been suggested that lung cancer mortality is increasing in Alaskan Native Americans as well.[6,7] Information on the use of tobacco products such as snuff and chewing tobacco by Native Americans in North Carolina is not available, although several reports indicate high prevalence of tobacco use among younger Native Americans elsewhere.[37–40]

It is recognized that the patterns reported in this study may reflect several biases. There is the possibility of racial misclassification bias in the mortality statistics, although its presence and magnitude have yet to be determined. Moreover, the age-specific population data for Native Americans in 1970 are only estimates. Diagnostic bias may also be present; however, the proportion of "other and unspecified" cancers has remained stable over time. The data also reflect coding under the eighth and ninth ICD; however, the two revisions are essentially identical for neoplasia. Perhaps of more concern, the data were aggregated across tribes which could obscure patterns of cancer mortality within tribes.

ACKNOWLEDGMENTS

The author is grateful to the North Carolina State Center for Health Statistics for providing access to the vital statistics data. All interpretations of these data are attributable to the author, who accepts full responsibility for any errors.

HUD Issues Guidelines on Lead-Based Paint Abatement

The US Department of Housing and Urban Development (HUD) has issued the first federal guidelines for the identification and abatement of lead-based paint in all public and Indian housing developments. The interim guidelines, signed by HUD Secretary Jack Kemp and published in the Federal Register, became effective April 1 and apply to all rehabilitation programs in public housing from that date forward. While the guidelines are recommendations and not mandatory, they represent the first national technical rules and procedures for testing, abatement worker protection, clean-up and disposal of lead-based paint in residential structures. The standards outlined in the 160-page document include several procedures for lead paint testing and removal that have proven effective in cities where lead abatement programs are mandated, such as Baltimore and Boston. Lead-based paint is believed to exist in about 40 million homes, or 40 percent of the country's housing stock where lead paint was used prior to 1970.

The federal guidelines recommend three accepted abatement strategies: complete replacement of all lead-painted surfaces, encapsulation or sealing of lead-painted areas, or paint removal. The guidelines outline the various methods of paint stripping, sanding and chemical processing, and the appropriate precautions to be taken with each, including daily and final clean-up. Proper clean-up procedures involve a thorough vacuuming, using a High Efficiency Particulate Air (HEPA)-filtered vacuum, followed by wet wiping with a high-phosphate solution, followed by a second HEPA vacuuming. The guidelines also recommend that sanding flat surfaces should be done with a sander attached to a HEPA vacuum that can collect the dust particles as they are released. Nilfisk of America, Inc., of Malvern, PA, one of the nation's leading manufactures of HEPA-filtered vacuums used in removal of lead, asbestos, silica, fiberglass and other harmful dusts, was asked by the National Institute of Building Sciences to participate in drafting the rules and recommendations that formed the basis for HUD's interim guidelines. For further information, contact HUD Headquarters, 451 7th Street, SW, Washington, DC 20410. Tel: (202) 755-6422.

Defining Arthritis and Measuring Functional Status in Elders: Methodological Issues in the Study of Disease and Physical Disability

ANDREW A. GUCCIONE, PHD, PT, DAVID T. FELSON, MD, MPH, AND JENNIFER J. ANDERSON, PHD

Abstract: This study explores the degree to which the association of knee osteoarthritis with physical disability changes with different definitions of osteoarthritis in 1,416 Framingham Study elders. When all categories of radiographic osteoarthritis were aggregated into a single "arthritis" variable and dependence upon human assistance in one or more functional activities combined into a single variable, elders with osteoarthritis had only moderately increased odds for dependence after controlling for age or sex (OR = 1.25). A definition of osteoarthritis based only upon symptoms produced larger odds for dependency (OR = 1.85). Elders with mild osteoarthritis and infrequent knee pain had no significantly elevated risk for dependence in any of the seven functional activities. Elders with infrequently symptomatic, moderate to marked radiographic osteoarthritis were at increased risk for dependence in stair climbing, walking a mile, housekeeping, and carrying bundles. Elders with radiographic osteoarthritis accompanied by frequent pain had an increased odds of dependence in stair climbing, walking a mile, and housekeeping. Using a generic definition of "arthritis" and aggregating functional activities may underestimate the impact of osteoarthritis on physical disability in the elderly and obscure the task-specific nature of that relationship. (*Am J Public Health* 1990; 80:945–949.)

Introduction

Diseases are often defined broadly in epidemiologic studies of the elderly and ascertained by self-report and clinical proxy measures such as symptoms. Using "arthritis" as a generic term, previous studies have provided broad insights into the relation between "arthritis" and disability.[1–4] These results do not necessarily provide us with information that captures the relation of a particular type and severity of arthritis or arthritic symptoms to functional limitations. Osteoarthritis refers to a specific pathological process within joints which is well-captured by radiographs that can be used to grade disease severity. The presence or absence of joint symptoms creates another dimension of disease definition.

A second issue in the study of disease and disability that requires examination is specification of the functional outcome. Combining several kinds of functional items into a single index for an overall score to estimate prevalence of disability[5–9] may be justified when the disease affects functional activities globally (e.g. the effects of stroke on activities of daily living) or when the summary score aggregates functional tasks of the same biomechanical or sensorimotor type (e.g. hand dexterity). However, a summary score may obscure the impacts of a disease on specific functional activities, particularly if many of the other activities included in the index are relatively unaffected by that disease.

Osteoarthritis is the most common form of arthritis in the elderly, and osteoarthritis of the knee is commonly associated with clinical symptoms and disability.[10] The first purpose of this study is to identify how the association of knee osteoarthritis with physical disability among elders changes using specific radiographic grades of osteoarthritis and the presence of symptoms to define the disease. The second purpose is to use these definitions to explore the association of knee osteoarthritis with discrete limitations in particular functional activities.

Methods

Study Population and Sample

The study population was the Framingham Heart Study cohort, a population-based cohort of the adult residents of Framingham, Massachusetts, designed to investigate factors associated with cardiovascular disease, and examined biennially since 1948. The prevalence of knee osteoarthritis during the 18th biennial examination (1983–85) has been reported elsewhere.[11] There were 1,826 participants in examination 18, of whom 1424 received knee radiographs. Eight persons were excluded from the present study; four with bilateral total knee replacements, another four with rheumatoid arthritis, leaving 1,416 cohort members.

Definitions of OA and Pain

Osteoarthritis (OA) was graded by an academically based bone and joint radiologist using the criteria of Kellgren and Lawrence:[12] grade 0 = normal radiograph; grade 1 = possible osteophytes; grade 2 = definite osteophytes; grade 3 = osteophytes and joint space narrowing; and grade 4 = large osteophytes, marked narrowing of joint space and definite deformity. Most studies have used grade 2 (the presence of definite osteophytes) as the criterion for defining disease, while a few others have required evidence of joint space narrowing (grade 3), corresponding to clinical definitions of disease, to designate osteoarthritis.[10] The radiographic grade for each subject in this study was assigned according to the most severely affected knee. Using the approach of the first National Health and Nutrition Examination Survey,[13] symptoms were defined as pain in or around the knee lasting at least a month within the previous year. Respondents who had either no symptoms or who may have had only infrequent pain were designated as asymptomatic.

We created three different definitions of radiographic osteoarthritis: asymptomatic grade 2 osteoarthritis, asymptomatic ≥ grade 3 osteoarthritis, and symptomatic ≥ grade 2 osteoarthritis. Subjects with symptoms were classified as those without radiographic evidence of disease and those with ≥ grade 2 osteoarthritis.

Measures of Physical Disability

Data were collected on 16 measures of physical disability at examination 18. Six items measuring the most basic activities of daily living were rejected for inclusion as we found little disability on these items, typical in a sample of

elders living independently in the community. Another three items measuring more complex activities were rejected for similar reasons. Of the seven remaining functional measures, two items covered activities explicitly involving the lower extremities: walking up and down a flight of stairs, and walking a mile; each of these items was adapted from the Rosow-Breslau Functional Health Index,[14] and had been used previously at Framingham. Five measures covered functional tasks requiring both upper and lower extremity use: housekeeping, heavy home chores including shoveling snow and washing windows, cooking, grocery shopping and carrying bundles weighing 10 pounds. The item on heavy home chores came from the Rosow-Breslau Functional Health Index; the last item was taken from an instrument developed by Nagi[15]; the items on housekeeping, cooking, and grocery shopping had been previously used at Framingham.[16]

Items from the Rosow-Breslau were recorded as able or unable to do without help. The items on housekeeping, cooking, and grocery shopping asked whether the respondent could perform that task entirely without help from another person. The item on carrying bundles was part of a physical performance battery administered by a trained nurse. It was scored as independent, dependent upon an assistive device, dependent upon human assistance, or unable to do. In order to make the definition of the dependent variable comparable across items, the need for human assistance was chosen as the criterion of disability on all seven dependent variables.

Data Analysis

We calculated two sets of prevalence odds ratios for dependence in performing each of the seven functional activities using logistic regression analyses, controlling for age as a continuous variable and sex. An odds ratio was defined as the relative odds of functional dependence among subjects with a specific definition of knee osteoarthritis divided by the relative odds of functional dependence among subjects without knee pain or osteoarthritis. The first logistic regression model explored odds for those elders with radiographic osteoarthritis. The second model explored odds for those elders with symptoms or symptoms plus radiographic disease.

Results

The age and sex of the subjects in our sample are described in Table 1. There were 589 men and 827 women in our sample (mean age = 72.7 years). There were 214 subjects with asymptomatic grade 2 osteoarthritis, 151 with asymptomatic osteoarthritis ≥ grade 3, 103 with knee pain and at least grade 2 osteoarthritis, and 57 with knee symptoms but no radiographic evidence of disease; 891 elders without knee pain or radiographic osteoarthritis served as controls. Due to missing data on functional measures, the number of elders in each of these groups is slightly lower in the results reported below.

The results of aggregating all radiographic osteoarthritic categories or using symptom reports as exposure variables while combining dependence in one or more functional activities into a single dependent variable are displayed in Table 2. Based upon these data, 37.5 percent of the subjects with osteoarthritis were dependent in one or more ADL compared to 29.8 percent of their peers without osteoarthritis. Furthermore, elders with osteoarthritis had only modestly increased odds for dependence in one or more functional activities after controlling for age and sex. Using a symptom-based definition of osteoarthritis, without respect to radiographic disease, showed an even larger proportion of disabled elders (46.2 percent). These elders had significantly increased odds for dependency in one or more functional activities. Using specific definitions of osteoarthritis and disaggregating functional measures, however, demonstrated quite different results.

The odds ratios for dependence upon human assistance to perform the two lower extremity activities are shown in Table 3. Overall, the elders in our sample exhibited little dependence in either activity. There were, however, substantially more elders in both the osteoarthritis and nonosteoarthritis groups dependent in walking a mile (14.2 percent) than dependent in stair climbing (3.2 percent). Combining all specifications of osteoarthritis into a single category reveals an increased odds ratio of dependence in each of these activities. Analysis by radiographic grade, however, demonstrates substantially lower and odds ratios for those elders with asymptomatic grade 2 osteoarthritis. Subjects with symptomatic osteoarthritis or asymptomatic osteoarthritis ≥ grade 3 had substantially increased odds for dependence in both lower extremity ADL. Elders who were classified as "arthritic" using symptom-based definitions had moderately increased odds for dependence in both lower extremity tasks.

Table 4 displays the odds ratios for dependence in each of the five complex ADL that combine both upper and lower extremity function. The largest proportion (27 percent) of disabled elders was found among those who relied upon human assistance for heavy home chores; there was little functional dependence among our subjects in the other four activities.

Considering all elders with any radiographic osteoarthritis as a single group showed very modest increased odds for dependence in any complex ADL. Subjects with asymptomatic grade 2 osteoarthritis showed no increased odds for dependence in these five activities. Elders with asymptomatic OA ≥ grade 3 had increased risks for dependence in housekeeping and carrying bundles. The odds for dependence among elders with symptomatic radiographic disease

No radiographic OA	12/55	(21.8)	2.16	(1.08, 4.31)
≥ grade 2 OA	30/101	(29.7)	2.87	(1.75, 4.70)

were slightly elevated in four of these tasks. The largest increased odds for dependence in complex ADL except cooking were found for those elders with knee pain but without radiographic disease.

Discussion

These results indicate the need for a specific definition of disease in the study of arthritis and disability in the elderly. Studying generic "arthritis" may underestimate the impact of osteoarthritis on physical disability in the elderly and obscure the task-specificity of that relationship. Our data demonstrate that dependence associated with knee osteoarthritis varies according to the criteria used to define osteoarthritis and show that knee osteoarthritis does not affect all types of functional activities equally. The magnitude of risk is clearly diminished when all degrees of osteoarthritis are combined, or minor radiographic changes are counted as osteoarthritis. Conversely, the odds are higher when definitions based upon symptom reporting are used. Our findings may help to explain the results of other studies. For example, a previous study of hand function and disease severity by Baron and colleagues[7] found little relationship between osteoarthritis severity measured radiographically and hand function. These investigators included all subjects with radiographic changes ≥ grade 2 in a single "osteoarthritis" category, which may explain the lack of association.

Summated indices of function that include many items unaffected by osteoarthritis may obscure the highly task-specific nature of these limitations, which, in the case of knee osteoarthritis, appear confined primarily to the lower extremity. The task specificity of osteoarthritis-related disability may explain the findings of Summers and coworkers[17] in their study of hip or knee osteoarthritis and functional disability in the elderly. Using 11 subscales from the Sickness Impact Profile (SIP), these investigators noted that only the correlation between disease severity and the SIP ambulation subscale was significant. This finding corroborates our own regarding the task-specific impacts of knee osteoarthritis on elderly function.

TABLE 4—Odds Ratios for Dependence upon Human Assistance to Perform Complex Activities of Daily Living by Grade of Osteoarthritis and Presence of Knee Pain Adjusted for Age and Sex

Activity	Proportion Disabled	(%)	Adjusted OR	(95% CI)
Housekeeping				
All subjects	71/1218	(5.8)		
No OA, no knee symptoms	42/799	(5.3)	1.0	
All Radiographic Grades ≥ 2	29/419	(6.9)	1.12	(0.68, 1.85)
Asymptomatic grade 2 OA	5/196	(2.6)	0.39	(0.15, 1.01)
Asymptomatic ≥ grade 3 OA	14/132	(10.6)	1.80	(1.93, 3.48)
Symptomatic ≥ grade 2 OA	10/91	(11.0)	1.86	(0.88, 3.92)

Asymptomatic grade 2 OA	8/196	(4.1)	0.79	(0.36, 1.77)
Asymptomatic ≥ grade 3 OA	7/126	(5.6)	1.06	(0.45, 2.51)
Symptomatic ≥ grade 2 OA	5/90	(5.6)	1.10	(0.41, 2.93)
All Knee Symptoms	8/139	(5.8)	1.18	(0.52, 2.67)
No radiographic OA	3/49	(6.1)	1.47	(0.43, 5.09)
≥ grade 2 OA	5/90	(5.6)	1.05	(0.39, 2.85)
Carrying Bundles				
All subjects	46/1280	(3.6)		
No OA, no knee symptoms	24/838	(2.9)	1.0	
All Radiographic Grades ≥ 2	22/442	(5.0)	1.31	(0.71, 2.42)
Asymptomatic grade 2 OA	5/205	(2.4)	0.63	(0.23, 1.71)
Asymptomatic ≥ grade 3 OA	12/139	(8.6)	2.47	(1.15, 5.31)
Symptomatic ≥ grade 2 OA	5/98	(5.1)	1.26	(0.46, 3.48)
All Knee Symptoms	9/150	(6.0)	1.62	(0.72, 3.68)
No radiographic OA	4/52	(7.7)	2.88	(0.92, 9.07)
≥ grade 2 OA	5/98	(5.1)	1.18	(0.42, 3.29)

Our previous study of the prevalence of osteoarthritis indicated that the proportions of elders with symptomatic knee osteoarthritis and those with ≥ grade 3 changes increase with age.[10] The present study demonstrates that the dependence in functional activities associated with these particular specifications of knee osteoarthritis varies according to the severity of osteoarthritis and the presence of symptoms. Thus the age composition of the sample is a crucial component of the study of osteoarthritis and disability. Studies of predominately younger elders may not have a sufficient number of cases severe enough to discern the impact of knee osteoarthritis on function.

Aggregated indices of function may be too imprecise with respect to knee osteoarthritis to identify the particular

nature of the functional deficits even when the sample has a sufficient number of severe cases. This study underscores the critical importance of choosing functional measures that can identify disability and also be meaningful in terms of the range of tasks and activities typically performed by elders. Using items that measure complex ADL only, e.g. cooking, we would have been unable to capture much of the relationship of knee osteoarthritis to physical disability. The difficulty of choosing discriminating functional measures is further complicated when the research interest focuses on physical function across diseases. "Walking a mile" serves as a case in point. The results of this study indicate that this task successfully identifies osteoarthritis-related disability, at least among the relatively more severe cases. It is also intuitively applicable to other important diseases of the elderly, e.g. cardiovascular diseases, but one must question how meaningful as an essential basic task walking a mile is within the context of an elder's daily activity.

The association of knee osteoarthritis and knee pain with lower extremity disability is not surprising. It is not clear, however, why severe knee osteoarthritis (≥ grade 3) should also be associated with limitations in housekeeping and carrying bundles, and not with other complex ADL. Biomechanical analyses of joint function and studies of muscle performance during these tasks may uncover why this particular degree of joint changes affects these ADL, but not others. Possibly these tasks also reflect choices made by elders. Functional activities are also sociological phenomena, not merely indicators of physical capacities for activity or disease outcomes. It is usually not a cultural expectation or a personal necessity to do heavy chores such as shoveling snow. On the other hand, elders may have little choice with regards to preparing their own meals. Light housekeeping and carrying bundles may be two tasks which elders can elect to perform, and therefore are sensitive to mild disability in elderly populations.

Our study indicated that a substantial number of elders without frequent symptoms had increased odds of disability. This association may be explained, in part, by the wording of our symptom question which required pain to persist for most days of a month. Pain in osteoarthritis is typically elicited by movement of the joint. Therefore, those elders with asymptomatic osteoarthritis ≥ grade 3 may be asymptomatic precisely because they avoid the tasks that would exacerbate the symptoms. If this is the case, then the impact of symptomatic radiographic disease on complex ADL may easily be underestimated given the transient activity-induced nature of pain in osteoarthritis. Questioning subjects on the presence of pain when performing each task might be more productive in demonstrating a relationship among osteoarthritis, pain, and functional disability.

Our data indicate that using knee pain as a proxy measure of arthritis, as might be done in studies using self-reported arthritis, has strengths and weaknesses. Defining osteoarthritis on the basis of symptoms alone did manage to capture many individuals with radiographic evidence of disease. The 57 elders reporting knee pain without radiographic disease may have had other related knee problems (e.g. anserine bursitis, patelofemoral disease, or referred pain from the hip), which are relevant to the study of musculoskeletal impairment and physical disability. Constructing the definition of arthritis solely on the grounds of knee pain, however, excludes a substantial number of subjects with radiographic disease but infrequent symptoms who also had physical disability. Investigators who do not use radiographs to corroborate self-reported arthritis should evaluate whether this degree of imprecision in classifying patients is consistent with their research goal.

In any case, the presence of symptoms should not be considered a necessary condition for exploring arthritis-related disability, a comment previously made with respect to the format of the National Health and Nutrition Examination Survey I.[18] Similarly, pain and functional limitations also should be explored separately in a clinical encounter.

Comorbidities, which are potential confounders of the association of knee osteoarthritis and physical disability, were not included in the model used to estimate odds ratios in this study. Our previous work has indicated a strong association between marked obesity and knee osteoarthritis.[19] The association of knee osteoarthritis with other conditions such as angina and diabetes, which are themselves associated with physical disability, is unclear and we are currently investigating this issue. Although the magnitude of the association between knee OA and physical disability may change in a more complete model, we do not anticipate that the distinctions found when using different definitions of osteoarthritis will be eradicated.

The disability prevalence estimates of our study are limited to those Framingham elders who were able to appear at the study site for a knee radiograph. Therefore, these estimates do not reflect the disability of elders who were home-bound or institutionalized and more likely to be functionally limited.

Although the present study confined itself to knee osteoarthritis, the methodology of this study is applicable to the study of other diseases. Defining diseases broadly, e.g. "stroke," "pulmonary disorders," or "cancer," allows only for a crude approximation of the relationship between disease and disability in the elderly. Symptomatology in other important medical conditions is also activity-induced. Elders with angina, emphysema or intermittent claudication may have learned over time which activities exacerbate their symptoms. These individuals may readily report that they have not recently experienced symptoms, yet have severely curtailed their level of functional activities. Analyses that contribute to our understanding of physical disability in elders by differentiating subgroups of disease and identifying their associations with particular functional limitations are an essential step in designing effective clinical interventions to remediate these deficits.

In summary, combining all severities of osteoarthritis into "arthritis," on using symptom-based definitions of disease alone, and aggregating all functional activities into a single measure of function obscures two facts: 1) that the degree of association between osteoarthritis and physical disability and the elderly depends on the definition of osteoarthritis; and 2) that the impact of any definition of osteoarthritis on functional status is highly task-specific. Future studies of the relationship of arthritis and physical disability in elders should use specific definitions of osteoarthritis and report the impact of specific severity levels of disease on particular functional activities. Such precision should also benefit our understanding of the relationship of other diseases and physical disability as well.

Two New Publications Available from MCH Clearinghouse

Two new publications which address the health of mothers and babies have been announced by the Health Resources and Services Administration of the federal government.

- *Nutritional Management of the Pregnant Adolescent: A Practical Reference Guide* is a 182-page manual on how to improve the nutrition of prospective young mothers and thus promote the birth of healthy babies. The manual was published through the joint efforts of HRSA's Maternal and Child Health Bureau, the US Department of Agriculture, and the March of Dimes Birth Defects Foundation.
- *Recommendations from the National Symposium on Genetic Services for Underserved Populations* is a new 41-page booklet based on the recommendations drafted at a symposium in May 1989, urging improved genetic services for the underserved. The symposium was sponsored by the Mid-Atlantic Regional Human Genetics Network and the March of Dimes Birth Defects Foundation; publication of the document was supported by the Health Resources and Services Administration.

Single copies of these publications are available from the National Maternal and Child Health Clearinghouse, 38th and R Streets, NW, Washington, DC 20057. Tel: (202) 625-8410.

The Present and the Future of AIDS and Tuberculosis in Illinois

TIMOTHY R. COTÉ, MD, MPH, MERWYN R. NELSON, PHD, SHARON P. ANDERSON, BA, AND RUSSELL J. MARTIN, DVM, MPH

Abstract: The relation between the acquired immune deficiency syndrome (AIDS) and tuberculosis (TB) was examined by matching the Illinois AIDS and TB registries. The match group was examined and compared with patients with only one disease by race, method of human immunodeficiency virus (HIV) transmission, site of tuberculous disease, radiographic findings, and results of Mantoux tests. The time of TB diagnosis was centrally distributed around the time of AIDS diagnosis; from this, it was determined that 4.1 percent of AIDS patients develop active TB. Projections for future AIDS cases were made by fitting a polynomial model to historical data. These projections were then used to predict the future impact of AIDS-related TB upon state TB rates. The rise in TB rates call for special efforts to minimize this impact. (*Am J Public Health* 1990; 80:950–953.)

". . . many of those who had been long gradually declining took to bed with symptoms of phthisis; in many cases of a formerly doubtful character the disease then became confirmed; in these the constitution inclined to the phthisical. Many, and in fact the most of them, died. . ."

—Hippocrates[1]

Introduction

Since the time of Hippocrates, a special susceptibility to clinical tuberculosis (TB) by those already infirm has been noted again and again. Patients with pre-existing malignancy, silicosis, or renal failure, and those undergoing corticosteroid therapy are all at increased risk for developing TB.[2] Two millennia of clinical observation and recent advances in cellular immunobiology[3] support the same generalized conclusion: insult to the salubrity of the human organism predisposes to TB. Reports that patients with the acquired immune deficiency syndrome (AIDS) are at increased risk for TB are consistent with this principle.

Since 1983, data regarding the AIDS/TB connection have come from hospital patient lists or population-based disease registries. In several studies (see Appendix) it has been possible to determine the proportion of persons with AIDS who develop TB[4–12]; the variation in this figure may reflect variation in the prevalence of tuberculosis infection among human immunodeficiency virus (HIV) transmission categories. In the populations studied to date, AIDS patients who are intravenous drug users or Haitian appear to be at higher risk for TB than other AIDS patients. The experience of central regions of the United States is important to an evaluation of the likelihood of a national resurgence of TB.

This paper reports the co-occurrence of AIDS and TB in Illinois, projections of future AIDS and AIDS/TB cases, and a strategy for control of AIDS-related tuberculosis.

Methods

Using a hybrid method of computerized and manual review, in September 1988 the electronic TB Registry for the State of Illinois was matched to the Illinois AIDS Registry. All TB and AIDS cases met the definitions established by the Centers for Disease Control and in effect at the time the diagnosis was made.[13,14] The electronic TB Registry contained 3,033 cases of TB diagnosed in Illinois from January 1985 to July 1988. By September of 1988, the records of all persons reported to the State in the calendar years 1986 and 1987 and some persons reported in calendar years 1985 and 1988 had been entered into the TB Registry and the AIDS Registry contained all 1,992 AIDS patients reported from 1980 through August 1988. An independent evaluation[15] of the Chicago portion of the AIDS Registry indicated that completeness of reporting was 95 percent.

Three fields were used to match TB Registry cases with AIDS Registry cases: last name, first name, and date of birth. Last names and dates of birth were considered critical fields. To be considered a match, one pair of critical fields had to match exactly and the other pair could vary by no more than a single character or a transposition. Additionally, during manual review first names had to be meaningful equivalents. Exact matches on dates of birth and last name were identified using a personal computer; satisfaction of the match definition was assured by manual review of the computer output.

The projected number of Illinois AIDS cases for 1988 through 1993 was obtained by fitting a third order polynomial ($y = \beta_0 + \beta_1 \times + \beta_2 \times^2 + \beta_3 \times^3$) to the case count from 1981 through 1987 and determining the 95 percent confidence intervals around the model.[17,18] "Y" represents the number of cases, "X" the year of projection, and each "β" is a constant coefficient. Goodness-of-fit was measured by the R squared statistic.

Comparisons of patient characteristics predisposing to AIDS were done using Yates-corrected chi-square analysis.

Results

A comparison of all AIDS and TB cases yielded 46 persons with both diseases. A profile of the characteristics of AIDS patients with and without TB is displayed in Table 1. Mantoux test results were available for 20 of these 46 patients; 13 (65 percent) were positive. AIDS patients who were Black were at increased risk of developing tuberculosis (RR = 2.65, 95% CI = 1.50, 4.69) as were persons who had intravenous drug abuse as a risk factor (RR = 1.72, 95% CI = 1.06, 3.49). After stratification, the effects of Black race and HIV were independently significant. Residence and sex were not significantly associated with the development of TB in AIDS patients.

Thirty-nine of the 46 persons (85 percent) with both diseases had pulmonary TB. Of these 39, chest x-ray results were available for 26 patients (66 percent); 18 (69 percent) of

these showed non-cavitary lesions, seven (27 percent) showed cavitary lesions, and one was within normal limits in a patient with positive cultures for *M. tuberculosis*. Seven persons (15 percent) with both diseases had only extra-pulmonary tuberculous disease, and 21 (46 percent) had only pulmonary tuberculosis. Thus 25 persons or 54 percent of cases with both TB and AIDS had extra-pulmonary involvement compared to 16 percent in TB patients nationwide.[16] Disseminated disease was miliary in six persons, involved cervical lymph nodes in four; involvement of gastrointestinal, genitourinary, other lymph nodes, and hematogenous sites occurred in two persons each, and tuberculous involvement of liver, brain, meninges and bone marrow each occurred in one case.

The distribution of intervals between time of TB diagnosis and time of AIDS diagnosis is symmetrical around the time of AIDS diagnosis. This distribution has a mean of .87 months and a standard deviation of 7.27 months. TB was diagnosed within six months of AIDS diagnosis in approximately 70 percent of persons with both diseases. This distribution is consistent with the findings of others[5,7] and forms the basis for the analysis below.

Because the Illinois TB Registry is complete for two consecutive years only, an analysis of limited time periods was performed to determine the fraction of TB patients who also contract AIDS and the fraction of AIDS patients who develop TB. TB Registry cases with TB diagnoses in calendar years 1986 or 1987 were compared to AIDS Registry cases with AIDS diagnoses from July 1, 1986 to June 30, 1987. After manual review of the 2,235 TB patients reported in 1986 or 1987 (years for which the electronic TB Registry held all TB reports), 104 incomplete or duplicate records were eliminated and 2,131 records remained. Of these 2,131 TB patients, 35 (1.6 percent) were also reported as having AIDS at some time from 1980 to 1987.

Persons diagnosed with AIDS from July 1, 1986 to June 30, 1987 (n = 603) could develop TB before or after calendar years 1986 and 1987. Therefore, the fraction of AIDS patients who contracted TB could not be calculated without including some adjustment for such TB cases. Comparison of the AIDS and TB intervals yielded 21 matches. Assuming that the distribution of onset intervals were normal with a mean and standard deviation of the observed distribution, the number of AIDS patients expected to develop TB before or after the two-year interval was calculated, yielding an estimate of four additional TB cases. Thus we estimate that 25 TB/AIDS cases occurred, of which four or 16 percent were undetected and that 4.1 percent of the 603 AIDS patients developed TB (95% CI = 0.0276, 0.0614).[17]

Projections of AIDS and TB/AIDS

Illinois AIDS case data were fitted to the above polynomial with the following coefficients: $\beta_0 = -41.2857$, $\beta_1 = 61.66666$, $\beta_2 = -23.25$, $\beta_3 = 4.083333$. The R squared statistic was .999305. The goodness-of-fit, projected AIDS cases and the 95% CI of the projections[18] are shown graphically in Figure 1.

Based on these projections, the centrally distributed AIDS/TB interval, and the proportion of AIDS cases who develop TB (4.1 percent), the number of AIDS patients with TB for each year from 1985 to 1993 was calculated (Table 2, column 4). Subtracting these cases from all TB cases reported and dividing by population figures yielded rates of non-AIDS associated TB (Table 2, column 5). Assuming an unchanged intensity in tuberculosis control measures and a constant 1988 level of non-AIDS associated TB, estimates of future rates for tuberculosis in Illinois can be projected (Figure 2).

Discussion

The reported diagnoses of tuberculosis in AIDS cases characteristically occur near the time of AIDS diagnoses, although this may reflect more careful examination rather than the co-occurrence of disease. The pattern of tuberculous organ involvement is bizarre in AIDS/TB, and radiologic findings are frequently atypical. While the Mantoux test result is often a false negative in AIDS/TB patients, the test remains a useful diagnostic tool.

The recent resurgence of TB in New York[7] and Florida[19] and the sudden arrest of the downward trend in US TB rates[20] have been clearly attributed to TB among AIDS cases. Without intensification of TB control measures, a similar rise in TB incidence can be expected in America's heartland.

The computed projections of TB in Illinois have several limiting deficiencies which need to be addressed. Determination of the proportion of AIDS patients who develop TB was based on a match of AIDS Registry cases who met the early definition of AIDS; the proportion of AIDS patients

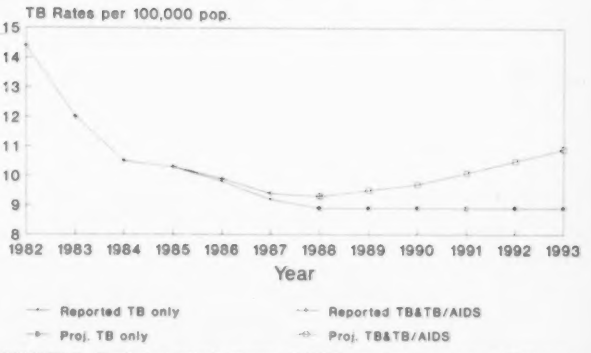

FIGURE 2—Projected Illinois Rates of AIDS-associated and non-AIDS-associated TB

who meet the broader 1987 definition may be different. The projection of future AIDS cases was based on empiric data and may be inaccurate. The assumption of an unchanging rate of tuberculosis unassociated with AIDS assumes no change in the characteristics of the population. The projections do not consider the effect of secondary transmission to uninfected individuals with or without AIDS by AIDS cases with TB. Finally, the projections only extend five years but the most serious public health impact of AIDS-associated TB may occur over the course of decades.

The Reports of the Advisory Committee for Elimination of Tuberculosis[21,22] provides an excellent blueprint for a strategy to minimize the impact of AIDS on future rates of TB. While of undocumented efficacy, early identification and prophylactic treatment of HIV-infected persons who are also infected with *M. tuberculosis* is a reasonable component of such a plan. Specifically, all intravenous drug users should be screened for both HIV and tuberculous infection. Regardless of age, isoniazid preventive therapy should be offered to all TB-infected persons who are intravenous drug users or HIV-infected. Greater utilization of the time-tested public health measures of contact tracing and targeted case finding is indicated at this critical juncture as the epidemiology of TB changes. Prompt recognition of this new group of infectious individuals will only be achieved by a heightened awareness by clinicians of the variegated presentations of TB in HIV-infected persons. Undoubtedly, these measures require a political conviction to confront the resurgence of a nearly vanquished disease and an allocation of resources commensurate with such conviction.

Agreements Signed to Establish European Center on Environment/Health

The WHO Regional Director for Europe, Dr. J. E. Asvall, signed agreements in mid-June with officials in Italy and the Netherlands to establish a European Center on Environment and Health, with units in Rome, Italy, and Bilthoven, Netherlands. Together the two units will form a single WHO Center which will become an integral part of the WHO Regional Office for Europe. By early 1991, each unit will have interdisciplinary teams of scientists and support staff and will be fully equipped to greatly expand the existing European program of WHO in the field of environment and health.

The proposal to establish a Center was made last year by the Frankfurt Conference when Ministers from 29 countries approved a European Charter on Environment and Health. One of the key recommendations was to carry out a feasibility study for such a Center and this was accomplished early in 1990. An agreement was reached to establish a single Center with units adjacent to the Institute for Public Health and Environmental Protection (RIVM) in Bilthoven, Netherlands and adjacent to the Institute of Public Health (ISS) in Rome, Italy. Both these institutions have an international reputation in the field of enviromental health and both will provide strong support to the Center.

A high priority for the Center will be to study the interrelationship between environmental effects and human health. The scientific work of the Center will cover a wide range of activities including health aspects of air and water pollution control, chemical and food safety, radiation protection and occupational health.

The Center will have an initial operating budget of about US $3 million per year and other European countries will be encouraged to actively participate in its work. Facilities are being provided both in Bilthoven and Rome for development of both long-term and short-term staff and for the holding of seminars and other meetings. Equipment will include advanced data processing facilities and there will be complete operational linkages with the WHO Regional Office in Copenhagen and with a wide range of scientific institutions and governmental centers.

The Relationship of Smoking Cessation to Coronary Heart Disease and Lung Cancer in the Multiple Risk Factor Intervention Trial (MRFIT)

JUDITH K. OCKENE, PHD, LEWIS H. KULLER, MD, DRPH, KENNETH H. SVENDSEN, MS, AND ELAINE MEILAHN, MPH, DRPH

Abstract: The impact of smoking cessation on coronary heart disease (CHD) and lung cancer was assessed after 10.5 years of follow-up in the 12,866 men in the Multiple Risk Factor Intervention Trial (MRFIT). Those men who died of lung cancer (n = 119) were either cigarette smokers at entry or ex-smokers; no lung cancer deaths occurred among the 1,859 men who reported never smoking cigarettes. The risk of lung cancer for smokers, adjusted for selected baseline variables using a Cox proportional hazards model, increased as the number of cigarettes smoked increased (B = 0.0203, SE = 0.0076). There was not the same graded response for CHD among smokers at entry. The risk of CHD death was greater among smokers than nonsmokers (RR = 1.57) (B = −0.0034, S.E. = 0.0048). After one year of cessation, the relative risk of dying of CHD for the quitters as compared to non-quitters (RR = 0.63) was significantly lower even after adjusting for baseline differences and changes in other risk factors. The relative risk for smokers who quit for at least the first three years of the trial was even lower compared to non-quitters (RR = 0.38). However, the relative risk for lung cancer for quitters versus non-quitters was close to 1 both for quitters at 12 months and at three years. These data support the benefits of cessation in relation to CHD and are consistent with other epidemiologic studies which suggest that the lag time for a beneficial effect of smoking cessation on lung cancer may be as long as 20 years. (*Am J Public Health* 1990; 80:954–958.)

Introduction

In the last two decades there have been continuing decreases in coronary heart disease (CHD) mortality rates in all United States populations[1–3] while lung cancer mortality rates continue to increase in certain populations.[4,5] Epidemiologic studies have consistently demonstrated a significantly higher relative risk for smokers compared to former smokers for each of these diseases.[1,2,6–8]

The beneficial effect of smoking cessation on CHD is rapid; as the period of cessation increases, the ex-smoker's relative risk approaches that of the never smoker.[3] However, in one study this return occurred gradually over a 20-year period.[8] The relative risk of developing lung cancer has been demonstrated to decrease as the period of cessation increases for smokers who have stopped smoking,[6–8] but their relative risk is still significantly elevated after 10 to 20 years of cessation compared to lifetime never smokers and is related to both the duration of smoking and length of cessation.[6–8]

In the available studies, the effect of smoking cessation on the risk of developing CHD and lung cancer was estimated either using data gathered retrospectively[6–8] or by considering that smoking habits were unchanged over the period of follow-up.[6,7] It is likely that during the course of these studies some ex-smokers became current smokers and vice versa. In addition, use of retrospective data entails problems of recall, and reports of cessation during the course of follow-up of these studies were not validated with biochemical measures. As a result, the mortality ratios reported for ex-smokers may be too high, and the benefits for cessation may actually be greater than those previously demonstrated for lung cancer and for CHD.

Using the detailed smoking behavior data gathered prospectively in the Multiple Risk Factor Intervention Trial (MRFIT), biochemically validated with serum thiocyanate measurements, we evaluated the relationship of smoking cessation to the development of CHD and lung cancer among middle-aged men, after 10.5 years of follow-up.

Methods

The MRFIT[9–21] was sponsored by the National Heart, Lung and Blood Institute (NHLBI) as a clinical trial, to test the effect of a multifactor intervention program on mortality from CHD. Other objectives included examination of decreases in other mortality and morbidity end points including lung cancer. In summary, the participants were 12,866 men ages 35–57 years at increased risk for CHD and free of overt CHD on entry. Men were designated at increased risk if their levels of the three major CHD risk factors—serum cholesterol, cigarette smoking, and blood pressure—were high enough at first screening to place them in the top 15 percent (later changed to 10 percent for 72 percent of the men screened) of a risk score distribution based on data from the Framingham Heart Study. Men with diastolic blood pressure of 115 mmHg or higher and those with total cholesterol of 350 mg/dl or higher were excluded.

Of the 12,866 men randomized to the special intervention (SI) and usual care (UC) groups, 64 percent (n = 8194) reported smoking cigarettes at the initial screening examinations, an average of 33.9 cigarettes/day. Randomization occurred from December 1973 to February 28, 1976. Thus, on February 28, 1982, when active intervention was terminated, each surviving man had been in the trial for at least six years, with a mean duration of 6.9 years of follow-up from randomization.

All SI men were encouraged and helped to make dietary changes directed at lowering their blood cholesterol levels. The smoking intervention program used an initial intensive group approach as well as individual counseling sessions when indicated. Both approaches included the use of behavioral and cognitive interventions. SI men who were hypertensive (mean diastolic blood pressure greater than or equal to 90 mm Hg on two consecutive visits, or on antihypertensive medication from their personal physicians) were treated with a stepped care approach.[13,18] UC men were not offered

© 1990 American Journal of Public Health 0090-0036/90$1.50

intervention at the clinical centers and were referred back to their usual source of medical care. They were asked to return to the MRFIT clinical center once a year for a comprehensive evaluation, including assessment of risk factors and morbidity status.

Baseline and annual data collection for both groups during the trial included a medical history and examination, information on past smoking patterns, and reported present cigarettes per day. Serum thiocyanate (Scn) was also measured at baseline and annually to validate reported smoking status. In addition to cigarette smoking, Scn may be elevated by the use of pipes, cigars and cigarillos, certain foods and diuretics.[22] Subjects with an Scn level of more than 100 μ mols/L were assessed to be smoking.

Mortality Ascertainment

During the trial and at termination of active intervention on February 28, 1982, deaths were ascertained by clinic staff through contact with family or friends of the deceased, routine follow-up of missed clinic visits, response to postcards requesting change-of-address information sent twice yearly to UC participants, and searches of publicly accessible files of deceased persons. The main source of vital status information after completion of participation in February 1982 has been the Social Security Administration and the National Death Index. Mortality ascertainment through December 31, 1985 was estimated to be approximately 100 percent complete using these data sources.[18]

The cause of death used in this report is based on death certificate reports. Cause-specific death rates are based on coding of death certificates by trained nosologists, according to the Ninth Revision of the International Classification of Diseases (ICD-9).[23] Each death certificate was independently coded by two nosologists and disagreements were adjudicated by a third nosologist. ICD-9 codes 410 to 414 and 429.2 were used to identify CHD deaths; ICD-9 code 162 was used to identify lung cancer deaths.

Statistical Methods

The SI-UC differences for the end points CHD and lung cancer mortality were tested for statistical significance using the log-rank test.[24] As in other MRFIT publications, 90 percent confidence intervals for the percentage difference in death rates are presented. Mortality rates are presented as number of cases per 1,000 person-years.

The relationship between smoking-related variables and end points was assessed for the combined MRFIT SI and UC smokers at entry into the study using the cox proportional hazards model.[25,26] In one analysis, smokers at entry who attended the first annual examination were classified as *quitters* if they reported not smoking at the first annual examination and had serum Scn levels that were less than 100 μ mols/L, or as *smokers*. In other analyses, smokers at entry who attended the first three annual examinations were classified as persistent quitters, if at each of the three annual examinations they reported not smoking and had serum Scn levels which were less than 100 μ mols/L at each visit, or as *other smokers/quitters*.

Relative risk (RR) estimates and 95 percent confidence intervals for quitters compared to non-quitters were calculated using the proportional hazards regression model. RRs are presented both unadjusted and adjusted for age, baseline blood pressure, cholesterol, number of cigarettes smoked per day, and years of education (as an index of socioeconomic status) added to the model as continuous variables. Differences in baseline characteristics and changes in risk factor levels from baseline to the third annual examination for persistent quitters compared to other smokers/quitters were tested for statistical significance using Student's t test.

Results

As of December 31, 1985, after an average period of follow-up of 10.5 years, there were 1,033 deaths in the MRFIT. There were 146 CHD deaths (3.42/1,000 person-years) among the SI smokers at entry and 165 (3.89/1,000 person-years) among the UC smokers at entry, a relative difference of −12.1 percent (90% CI = −27.1, 5.9). The CHD mortality rates were 2.26/1,000 person-years and 2.44/1,000 person-years for SI and UC non-smokers at entry, respectively. There were 56 lung cancer deaths (1.31/1,000 person-years) among the SI smokers at entry and 50 (1.18/1,000 person-years) among the UC smokers at entry, a relative difference of +11.3 percent (90% CI = −19.2, 53.3). The nine SI and four UC non-smokers at entry who died of lung cancer had been smokers at some point prior to entry into the study.

Mortality in Subgroups Defined after Randomization

Although smoking intervention in the MRFIT resulted in a significantly higher cessation rate for SI compared to UC men ($p < .001$), the lung cancer and CHD mortality rates were not significantly different for these two groups. (Smoking cessation results in the MRFIT will be presented in detail in a subsequent section.) The within group analyses presented in Tables 1–5 are observational, combining data for SI and UC participants.

No lung cancer deaths occurred among the 1,859 MRFIT men who had never smoked cigarettes. Among cigarette smokers there appeared to be a graded relationship between the number of cigarettes smoked per day at baseline, and the lung cancer mortality rate. However, number of cigarettes smoked per day at baseline and risk of CHD mortality did not appear to have as strong a relationship as for lung cancer. Ex-smokers appeared to have a risk of dying from CHD that approached that of never smokers (Table 1).

In the MRFIT study group, never smokers had higher cholesterol and/or blood pressure levels than smokers at baseline in order to be in the top 10 percent of CHD risk. Regression analyses to account for confounders shown in Tables 2 and 3 indicate that only age, the screen 1 cigarettes/day, and baseline Scn are of importance for lung cancer; for CHD mortality age, baseline Scn, DBP, and cholesterol were all significant risk factors ($p < 0.01$). Removing Scn from the regression analysis did not result in a significant relationship between number of cigarettes smoked and CHD risk among smokers.

TABLE 1—CHD and Lung Cancer Deaths and Mortality Rates per 1,000 Person-Years by Number of Cigarettes Smoked per Day at Baseline for MRFIT SI and UC Men Combined

		CHD Deaths		Lung Cancer Deaths	
	Total	N	Rate/1000 Person-Years	N	Rate/1000 Person-Years

CHD and lung cancer mortality rates for all men who quit smoking during the first year were compared with the rates of those who continued to smoke (Table 4). The total group of smokers who reported quitting in year one and had Scn < 100 μ mols/L had a relative risk of dying from CHD .63 that of non-quitters. The relative risk estimate adjusted for entry risk variables were similar to unadjusted estimates (Table 4). The quitters had the same lung cancer mortality rate from year one to the end of the trial as those who were non-quitters at year one (Table 4). (This was true regardless of baseline levels of smoking or whether they were in the UC or SI group.)

TABLE 4—Number of CHD and Lung Cancer Deaths and Mortality Rate (per 1,000 person-years) from the 12-month visit through 12/31/85[a] for Baseline Smokers by Smoking Status at 12 months, and Relative Risk Estimates (Quitters/Not Quitters) for MRFIT SI and UC Men

Smoking Status	# of Participants SI + UC	Deaths SI + UC	Relative Risk Quit/Not Quit (95% CI)	Adjusted Relative Risk[d] (95% CI)
		Coronary Heart Disease		
Quit[b]	1365	33 (2.54)[c]	.63 (.44,.90)	.58 (.40,.84)
Not Quit	6298	239 (4.04)		
		Lung Cancer		
Quit[b]	1365	17 (1.31)[c]	0.99 (.59,1.67)	1.05 (.62,1.79)
Not Quit	6298	78 (1.32)		

[a] This represents an average of 9.5 years of followup
[b] Quitters are S_1 smokers who reported no smoking at year 1 with SCN < 100 μ moles/L.
[c] Rates per 1000 person-years.
[d] Adjusted for age, baseline cigarettes/day, cholesterol, blood pressure, education

We also looked at persons who had quit smoking for at least the first three years of the trial (persistent quitters). Compared to the continuing smokers, the persistent quitters experienced a reduced risk of CHD death (RR = .38) but no change in risk of dying of lung cancer (Table 5). These comparisons are limited by the small number of quitters who persisted for three years which was less than the number who persisted for one year. (Participants who died in the first three years of the trial are also not included.) Persistent quitters were also lighter smokers than those who did not persist (average 30.1 vs 34.2 cigarettes per day).

Persistent quitters and continuing smokers had differences in baseline risk factors and in changes in other risk factors through the three years the two groups were compared. On average, persistent quitters smoked four fewer cigarettes per day and drank 2.2 fewer alcoholic drinks per week at baseline than did other smokers or short-term quitters. Persistent quitters experienced significantly greater weight gain by three years than other smokers or quitters. Adjusting for the differences in risk factors at baseline did not change the relative risk estimates (0.38 versus 0.35), nor did adjusting for the differences in risk factor changes (RR = 0.36, 95% CI = 0.20, 0.65). Likewise, none of these models produced changes in relative risk estimates for lung cancer.

The distribution of lung cancer deaths throughout the span of the trial does not indicate any difference in early versus late mortality by randomization status. Therefore, there is no evidence to date for a trend toward fewer SI as compared to UC lung cancer deaths as time from entry becomes longer, or closer to the 10.5 year maximum follow-up. Because of the relatively small number of participants who were long-term quitters of three or more years and died of lung cancer, it is not possible to evaluate whether the lung cancer death rates might be declining in the latter years of the trial among persistent quitters.

Cessation and Relapse Patterns

Although CHD and lung cancer mortality rates were not significantly different between the randomized groups, smoking cessation rates were significantly different for SI compared to UC men (Figure 1). The cross-sectional data indicate that, throughout the six years of follow-up in the trial, cessation rates for SI smokers were approximately 17 percentage points greater than they were for UC smokers.

TABLE 5—Number of CHD and Lung Cancer Deaths and Mortality Rate (per 1,000 person-years) from the 36-month visit through 12/31/85[a] for Baseline Smokers by Smoking Status at 36 months, and Relative Risk Estimates (Quitters/Not Quitters) for MRFIT SI and UC Men

FIGURE 1—Distribution of Smoking Cessation History for Each Annual Visit for Special Intervention(SI) and Usual Care(UC) Smokers.
***Smokers who maintained cessation from year one to the noted year of follow-up.**
****Smokers who stopped, relapsed and stopped again; or smokers who stopped after year one and remained off cigarettes.**
*****Smokers who had not previously reported cessation in the trial but stopped after noted annual examination.**

(Reported rates are used in Figure 1 because by year six there was very little discrepancy between the reported rates and the rates validated by serum Scn.) Cross sectional data do not indicate what proportion of smokers stopped and continued off for the duration of the trial. Cohort data (vertical striped bar) indicate that 25 percent of the SI smokers (60 percent of those who quit in year one) remained abstinent through year six of the trial. For the UC smokers, 6.9 percent (54 percent of those who quit in year one) remained abstinent through year six.

The three groups—maintained stoppers, recycled stoppers, and new stoppers—were calculated for light (<25 cigarettes/day) versus heavy (≥25 cigarettes/day) smokers for the SI and UC groups, respectively. There were lower cross-sectional cessation rates among heavy smokers compared to light smokers in both the SI and UC groups; an approximately two-fold difference in maintained cessation rates for light versus heavy smokers; and a four-fold difference for SI versus UC smokers. For example, only 19.4 percent of SI heavy smokers stayed off of cigarettes for the six years of the trial and only 5.2 percent of UC heavy smokers did so.

Discussion

Smoking cessation during the trial had a substantial and fairly rapid beneficial effect on CHD mortality. The lack of an observable beneficial effect of stopping smoking on lung cancer at the 10.5 year follow-up may in part reflect the long lag period associated with the development of lung cancer. The MRFIT data are consistent with observational studies of lung cancer and smoking cessation indicating that the effect of smoking cessation is related to length of cessation and that there is still a substantial increase in risk for lung cancer among former smokers even after relatively long periods of cessation when compared to never-smokers.[6–8] Given that the MRFIT smoking data were prospectively collected, biochemically validated, and substantially more precise than data from any previous epidemiologic study, they strengthen previous evidence reflecting the immediate beneficial effect of smoking cessation on CHD and the long lag period with respect to a potential beneficial effect on lung cancer.

The sample size estimate for the MRFIT was based on CHD end points and changes in multiple risk factors. Therefore, it was not designed to detect the specific effect of smoking cessation nor differences in lung cancer mortality, which has a lower incidence than CHD mortality. The 90 percent confidence interval bounds for the +11.3 percentage point difference in lung cancer mortality rates for SI compared to UC smokers ranged from −19.2 to +53.3 percent. It is therefore unlikely that a substantial effect (i.e., greater than 20–30 percent lower lung cancer mortality for SI smokers), was missed due to lack of power.

To our knowledge, the MRFIT is only the second intervention trial which has examined the relationship between lung cancer mortality and smoking in randomized groups. The first such trial was the Whitehall Civil Servants Smoking Intervention Trial carried out by Rose and his colleagues.[27] After 10 years of follow-up, there were 22 lung cancer deaths in the intervention group and 25 in the normal care group. Intervention subjects (N = 714) reported a significant net decrease of 7.6 cigarettes/day compared to the control subjects (N = 731) after nine years of follow-up. This trial did not have adequate power to detect a difference in lung cancer. In addition, no objective measures of smoking were obtained. There are no data available from this trial with regard to persistence of quitting or cessation and maintenance rates for heavy versus lighter smokers.

The data confirm results from studies indicating an overwhelming smoking effect on lung cancer risk, with a greater relative risk for heavier smokers as compared to lighter smokers.[1,2,4,6–8] We found no effect of tar or nicotine levels on lung cancer either by univariate or multivariate analysis, suggesting that smokers should not develop a false sense of security by switching to lower tar and nicotine cigarettes.

In previous analysis, we have shown that dose of smoking is an important CHD risk factor when MRFIT smokers and ex-smokers are combined.[13,18] However, the number of cigarettes smoked per day at entry had little effect on risk for CHD when the analysis was limited to smokers only. In part, this is due to the multifactorial etiology of CHD, and may also be related to the focus of MRFIT recruitment on high-risk men, yielding a skewed distribution with a preponderance of relatively heavy smokers. Using a multivariate Cox Proportional Hazard model, baseline Scn level, which is a better marker of acute dose of exposure to cigarettes than reported number of cigarettes smoked, had a significant effect on CHD risk among smokers.

Quitters tended to gain more weight than non-quitters. However, the differences were modest and did not affect the relative risk estimates for CHD of quitters compared to non-quitters when included in the model. CHD deaths did occur among never-smokers, also confirming the multifactorial etiology of CHD.[3,28–34] By the nature of the MRFIT inclusion criteria, those individuals who were non-smokers on entry into the trial had relatively higher levels of serum cholesterol and blood pressure.

In most studies, a large number of persistent quitters is not available to adequately test the relationship of smoking

cessation to reduction in death rates; and most persistent quitters are lower risk, lighter smokers. This lack of persistent quitters is likely to attenuate the relationship between cessation and risk. If many years of persistent quitting is required to produce a beneficial effect on lung cancer mortality rates, it will be difficult to carry out studies to demonstrate such an effect.

The disparity in the beneficial effects of smoking cessation observed in this study between lung cancer and CHD mortality may help to explain the disparity seen nationally between sharply decreasing CHD mortality rates and lung cancer mortality rates which show little change. The greater smoking prevalence in earlier birth cohorts also accounts in part for the persistent high lung cancer death rates in these older individuals. Furthermore, some older smokers may have avoided cardiovascular death by smoking cessation and may now be at high risk of lung cancer, further increasing the pool of lung cancer susceptibles.

Lung cancer continues to be a major public health problem. Prevention of smoking and cessation at the youngest possible age for those individuals already smoking are the most important determinants of the future trends of lung cancer mortality.

Onset of Fertility-Related Events during Adolescence: A Prospective Comparison of Mexican American and Non-Hispanic White Females

Carol S. Aneshensel, PhD, Rosina M. Becerra, PhD, Eve P. Fielder, MPH, and Roberleigh H. Schuler, BS

Abstract: Ethnic differences in the first occurrence of fertility-related events are assessed for non-Hispanic White and Mexican American female adolescents. A community-based sample of 1,023 females ages 13 to 19 years was interviewed in 1984–85; 874 (85.4 percent) were reinterviewed approximately two years later. Mexico-born Mexican Americans have the lowest rate of early sexual intercourse, but the highest rate of early births because they are most likely to become pregnant if sexually active, and most likely to have a birth if pregnant. Non-Hispanic Whites have the highest rate of early sexual intercourse, but the lowest rate of early births because pregnant non-Hispanic Whites terminate pregnancies most often. US-born Mexican Americans are intermediate between the other two groups. Delays in the onset of sexual activity among Mexican Americans are not converted into corresponding delays in first pregnancies and births. Early marriage among Mexico-born Mexican Americans, however, accounts for much of the ethnic difference in early fertility. (*Am J Public Health* 1990; 80:959–963.)

Introduction

The well-known health, social, and economic costs associated with teenage fertility have made the prevention of teenage pregnancy a public health priority, particularly in the context of comparatively high US rates.[1] The early initiation of sexual intercourse lengthens the period of risk for teenage pregnancy; an additional consideration is the high rate of sexually transmitted disease among teens and the associated risk of HIV (human immunodeficiency virus) infection. Comparison of intergroup differences in teenage sexual initiation, contraception, pregnancy, abortion, and fertility have focused almost exclusively on the substantial differences existing between Black and White adolescents.[1–5] Comparatively little research has examined early fertility-related behavior among Hispanics in general or among discrete Hispanic subgroups. Yet recent research indicates that fertility among teenagers of Hispanic or Latino ethnic background is closer to the high rate of Black teens than to the lower rate of non-Hispanic White teens.[6–12]

Information about discrete Hispanic groups is limited because Hispanics often are analyzed as a single, undifferentiated social group. Mexican-origin women, however, have markedly higher fertility rates than Puerto Rican and Cuban women.[9] Similar intraethnic heterogeneity apparently exists among teens and young women.[7–10]

For Mexican American females, rates of early sexual intercourse, contraception, and abortion appear to be relatively low, in contrast to comparatively high rates of early fertility. A 1979 household survey of four border states revealed that Mexican American teenagers (15 to 19 years) were less likely than non-Hispanic Whites to be sexually active, and that sexually active Mexican Americans were less likely than non-Hispanic White teens to contracept.[14] We have shown that a high birth rate among Mexican American teens can be attributed to a small base of sexually active females who become pregnant and who elect live births (rather than abortions) at rates higher than the comparatively large base of sexually active non-Hispanic Whites.[12] High early fertility rates among Mexican American females, therefore, may coincide with relatively low rates of early sexual intercourse as a result of especially low rates of contraception among sexually active teens and/or low rates of abortion among pregnant teens.

This report extends previous research by examining multiple fertility-related events (early sexual intercourse, pregnancy, live births, and abortions) utilizing a prospective panel survey of a community-based sample. It also examines differences between Mexican American adolescents born in the United States and those born in Mexico.

Methods

Sample

The data for this study were derived from two sets of interviews conducted with an area probability sample of Los Angeles County Mexican-American and non-Hispanic White adolescent females. Time 1 interviews were conducted between January 1984 and May 1985 and time 2 interviews between January 1986 and May 1987. The average interval between completed interviews was 23 months.

A three-stage cluster sampling frame was used to select respondents: census tracts, blocks, and household addresses. Mexican American adolescents were oversampled by sampling two strata of census tracts: those with a high density (17.8 percent or more) of Hispanics and those with a plurality of non-Hispanic Whites. Sampled household addresses were screened to determine eligibility, defined as being a female resident of the household between the ages of 13 and 19 years who self-identified as being either Mexican American, Mexican or Chicano, or as being White and not of the above or other Latin American background.

One eligible respondent per household was selected using a modified version of the Kish selection method.[15] Mexican American households were more likely than non-Hispanic White households to contain more than one eligible adolescent (29.9 percent versus 19.2 percent). The data were weighted to adjust for this selection probability, but unweighted data are reported, following the suggestion of Kish, because weighted and unweighted analyses are virtually identical.[15]

Of 19,258 field-listed addresses, 861 were unoccupied dwelling units, 721 were not successfully screened, and

16,552 screened households did not contain an eligible adolescent. Of the 1,124 known eligible households, 1,023 (91.0 percent) participated in the survey, 67 (6.0 percent) refused, and the remainder did not participate for other reasons. Of those interviewed, 874 (85.4 percent) were reinterviewed at time 2. Sample sizes for time 1 and time 2, respectively, are: 317 and 284 (90.0 percent) for non-Hispanic Whites; 398 and 358 (90.0 percent) for US-born Mexican Americans; and 308 and 232 (75.3 percent) for Mexico-born Mexican Americans. The cumulative response rate across time 1 and time 2 was 74.7 percent assuming proportional eligibility among unscreened households. The major source of attrition was an inability to locate participants who had moved, which accounted for 85.2 percent of the 149 nonrespondents. In addition, 10.7 percent were lost because of refusals, 1.3 percent were deceased, and 2.7 percent were lost for other reasons. Loss to follow-up was disproportionately high among Mexico-born Mexican Americans and among the sexually experienced, particularly those who had ever been pregnant.[16]

Detailed descriptions of the sampling procedures and characteristics of the sample are provided elsewhere.[12,16] The average socioeconomic status of the adolescent's family is lower for Mexican Americans than for non-Hispanic Whites, which conforms to census data for Los Angeles County.[17] In addition, the sample school dropout pattern conforms to ethnic patterns in the County.[18] In general, the characteristics of the sample are similar to those of the population from which it was selected.

Procedures

Interviews were conducted by professional female staff from the UCLA Institute for Social Science Research, Survey Research Center. Interviews lasted approximately one hour and were conducted in either English or Spanish. All of the time 1 interviews were conducted at the respondent's home, but 13.5 percent of the reinterviews were conducted by telephone, usually because the respondent had moved.

The interviews were similar at the two times and asked about a wide range of fertility-related attitudes and behavior; only a portion of the information obtained is reported here. The respondent's sexual status was ascertained by asking: "Sometimes people refer to sexual intercourse as 'doing sex,' 'having sex,' 'making love,' or 'going all the way.' Have you ever had sexual intercourse?" Respondents who answered in the affirmative were asked a series of questions concerning their sexual experiences including age of first intercourse and number of partners. Those who had ever been pregnant were asked whether each pregnancy mentioned resulted in a live birth, a stillbirth, a miscarriage, or an abortion.

Analysis

Lifetime prevalence estimates are based on the total sample at time 1, and on the reinterview sample at time 2. The combined age distribution for Hispanics and non-Hispanic Whites from the 1980 Census is used as the standard population to calculate sample weights for time 1 and time 2 that are equivalent to the direct standardization method of age-adjustment. Also, for prevalence estimates, the panel data are weighted to adjust for attrition utilizing a predicted probability of being reinterviewed.[19] Due to the complex sample, confidence intervals are probably slightly underestimated.

Survival analysis is employed for age of first intercourse, pregnancy, and birth because those negative on these events had not completed the period of risk. Those negative on events at reinterview are censored at their time 2 age, while those negative at time 1 and lost to follow-up are censored at their time 1 age. For nonmarital events, the married are censored at their age of marriage. Survival functions are evaluated through age 20 years. There are too few abortions across the age and ethnic groups to conduct meaningful analysis. Survival analyses were conducted with the BMDP Statistical Software program P1L.[19] The Savage-Mantel-Cox statistic is used to assess intergroup differences in the survival functions.[20]

Results

As shown in Table 1, the lifetime prevalence of sexual intercourse is substantially higher at follow-up than at base-

TABLE 1—Age-Adjusted Percent Sexual Intercourse, Pregnancy, Live Birth, and Abortion at Baseline and Follow-up by Ethnic Group

M-MA	0.5 (0.0, 1.3)	1.5 (0.0, 3.0)	3.2 (0.0, 8.1)	4.0 (0.2, 7.8)	5.0 (0.0, 12.6)	5.3 (0.2, 10.4)

NOTE: NHW = Non-Hispanic White; US-MA = US born Mexican American; M-MA = Mexico-born Mexican American. Time 2 percents are weighted to adjust for sample attrition. Live birth and abortion percents among the ever-pregnant do not sum to 100 percent because of repeated pregnancies, small numbers of spontaneous abortions, and current first pregnancies. Time 1, Unweighted N, Total Sample: NHW = 315; US-MA = 396; M-MA = 305; Sexually Experienced: NHW = 135; US-MA = 86; M-MA = 41; Ever Pregnant: NHW = 26; US-MA = 33; M-MA = 25. Time 2, Unweighted N, Total Sample: NHW = 281; US-MA = 358; M-MA = 227; Sexually Experienced: NHW = 157; US-MA = 176; M-MA = 74; Ever Pregnant: NHW = 44; MA-US = 72; M-MA = 52. 95% confidence interval in parentheses.

line for all three ethnic groups, as would be expected given that the sample has aged, on average, two years. The prevalence of sexual intercourse is substantially lower among Mexico-born Mexican Americans than among the other two groups, with non-Hispanic Whites having the highest lifetime prevalence of sexual intercourse at baseline and at follow-up.

The percent ever pregnant more than doubles across time for all three groups. Non-Hispanic Whites have the lowest rate of ever having been pregnant at both times, with US-born Mexican Americans and Mexico-born Mexican Americans having the highest rates at time 1 and time 2, respectively. At both times, however, the confidence intervals overlap for all three groups. Among only those who have ever had sexual intercourse, the percent ever-pregnant is substantially higher among Mexico-born Mexican Americans than among non-Hispanic Whites at both baseline and follow-up: US-born Mexican Americans are intermediate between these other groups. The increase across time is modest, indicating a similar risk of pregnancy.

For the percent ever having had a live birth, similar ethnic differences are observed for the total sample, those who have ever had sexual intercourse, and those who have ever been pregnant. This percentage is highest for Mexico-born Mexican Americans and lowest for non-Hispanic Whites. These ethnic differences are more pronounced for the sexually experienced and the ever-pregnant than for the total sample and tend to be somewhat more pronounced at follow-up than at baseline.

Ethnic group differences in abortion mirror the live birth pattern. Non-Hispanic Whites have the highest percent having had an abortion at both times and the greatest increase across time. Among the sexually experienced and the ever-pregnant, the percent who have had an abortion decreases over time among US-born Mexican Americans.

Non-Hispanic White female adolescents are substantially more likely than Mexican-American adolescents to have had multiple sexual partners, although the mode is one partner for all three groups. For non-Hispanic Whites, 29.7 percent have had only one partner, with 12.1 percent having more than 10 partners. For Mexican Americans, 48.9 percent of the US-born and 79.6 percent of the Mexico-born have had only one partner, with 10 being the maximum number of partners in both groups. This difference persists when the number of years of sexual activity is controlled statistically.

The survival functions for age of initiating sexual intercourse differ among the three ethnic groups (Savage-Mantel-Cox statistic = 47.25, d.f. = 2, $p < .001$). As shown in Table 2, the cumulative proportion surviving without initiating intercourse is substantially higher among Mexico-born Mexican Americans than among the other groups from the age of 15 years onwards. The median survival age is substantially older among Mexico-born Mexican Americans (19.7 years) than US-born Mexican Americans (17.8 years), or non-Hispanic Whites (17.4 years).

The hazard rates, the probability of first intercourse at a specific age given no intercourse before that age, also differ by ethnic group, as shown in Table 2. For non-Hispanic Whites and US-born Mexican Americans, marked increases occur between the ages of 15 and 17 years. For the Mexico-born, the hazard rate increases substantially between 17 and 19 years. The peak hazard rate for all three groups is between 18 and 19 years.

Contrastingly, the survival functions for age of first pregnancy are similar across these three groups (Savage-Mantel-Cox = 3.37, d.f. = 2, $p > .10$). The decline in the proportion surviving without a pregnancy is somewhat more marked among the two Mexican American groups than among non-Hispanic Whites, as shown in Table 3. For both Mexican American groups, hazard rates are relatively low until a sharp increase occurs between 17 and 18 years. For non-Hispanic Whites, the hazard rate increases approximately a year later.

Despite similar patterns for pregnancy, there are substantial ethnic differences in the survival functions for first birth (Savage-Mantel-Cox statistic = 13.30, d.f. = 2, $p < .005$). As shown in Table 4, the cumulative proportion surviving without a live birth is similarly high across ethnic groups until age 17 years, and thereafter declines more rapidly among the two Mexican American groups than among the non-Hispanic White group. The pattern for the two Mexican American groups is similar until age 18; thereafter the proportion surviving declines more among the Mexico-born than among the US-born. For non-Hispanic Whites, the hazard rate is highest between the ages of 17 and 18 years. At this age, the Mexican-American groups have a similar hazard rate, but this rate increases further over time.

Ethnic differences in early marriage may contribute to these patterns. The percent ever-married is substantially higher among Mexico-born Mexican Americans (14.3 percent) than among US-born Mexican Americans (6.5 percent) or non-Hispanic Whites (4.7 percent). Moreover, among the ever-married, the Mexico-born are most likely to have married prior to first sexual intercourse, pregnancy, and live birth. For US-born Mexican Americans and non-Hispanic Whites, prevalence rates for nonmarital fertility events are quite similar to those for all events. For Mexico-born Mexican Americans, however, the prevalence rates for nonmarital events are substantially lower than all events. The

20	.832 (.049)	.674 (.052)	.643 (.060)	—	—	—

NOTE: Standard errors in parentheses. NHW = Non-Hispanic White, N = 313; US-MA = US-born Mexican American, N = 395; M-MA = Mexico-born Mexican American, N = 299.

cumulative proportion surviving to age 20 years without nonmarital intercourse is .183 (SE = .046) for non-Hispanic Whites, .201 (SE = .050) for US-born Mexican Americans, and .637 (SE = .046) for Mexico-born Mexican Americans (Savage-Mantel-Cox Statistic = 72.25, d.f. = 2, $p < .001$; see Table 2). For nonmarital pregnancy, the three ethnic groups remain similar (Savage-Mantel-Cox Statistic = 3.73, d.f. = 2, $p > .10$), with the proportion surviving to age 20 years being .673 (SE = .060) for non-Hispanic Whites and .616 (SE = .057) for Mexico-born and .695 (SE = .070) for US-born Mexican Americans (see Table 3). In contrast, the survival functions differ by ethnicity for nonmarital births (Savage-Mantel-Cox Statistic = 9.49, d.f. = 2, $p < .01$), with the cumulative proportion surviving to age 20 years being .869 (SE = .048) for non-Hispanic Whites, .772 (SE = .043) for US-born Mexican Americans, and .876 (SE = .052) for Mexico-born Mexican Americans (see Table 4).

Discussion

In sum, non-Hispanic Whites have the lowest level of early fertility despite having the highest level of sexual activity because sexually experienced non-Hispanic Whites are the least likely to become pregnant and because pregnant non-Hispanic Whites are most likely to elect abortion. In sharp contrast, Mexico-born Mexican Americans have the lowest level of early sexual intercourse, but are most likely to become pregnant if they have sexual intercourse, and most likely to have a birth if they become pregnant. Consequently, the Mexico-born have the highest fertility rate. US-born Mexican Americans tend to be intermediate between the other two groups across the various events studied. Age of first pregnancy is similar across the three ethnic groups, but Mexico-born Mexican Americans initiate sexual intercourse at later ages than the other two groups, and both Mexican American groups have first births at earlier ages than non-Hispanic Whites.

The role of early marriage in fertility-related events is most pronounced among Mexico-born Mexican Americans. Only a small proportion of young women in any of these groups marry early, but the somewhat greater propensity of Mexico-born Mexican Americans to do so accounts for most of the difference in early fertility in comparison to non-Hispanic Whites. Early marriage, however, does not account for differences in early fertility between US-born Mexican Americans and non-Hispanic Whites. Thus, while Mexico-born Mexican Americans are most likely to have early births overall, US-born Mexican Americans are most likely to have early nonmarital births.

The estimates of early fertility obtained in this investigation for Los Angeles County females are somewhat below the national estimates provided by Michael and Tuma.[6] These differences may be due to regional effects, the later study date of the present investigation, differences in study procedures, or variation within the Hispanic population. In general, the age-specific rate of first births (see Table 4) closely approximates the 1980 age-specific fertility rate for Los Angeles County for Hispanics and for non-Hispanics Whites.[11] These rates are not directly comparable for a variety of reasons. Nonetheless, this similarity suggests that underreporting of live births by study participants is not a serious source of misestimation.

These data reveal substantial potential risk for adolescent females for transmission of HIV infection or other sexually transmitted disease through multiple sexual partners. All else being equal, non-Hispanic White females would

be at highest risk because they have the highest rate of early sexual intercourse and are most likely to have multiple sexual partners. While the relative risk of AIDS is higher among Hispanic than non-Hispanic White men, this higher risk appears limited to Puerto Ricans rather than Mexican Americans.[21] Assuming within-group selection of sexual partners, young Mexico-born Mexican American females, therefore, would appear to be at low risk, due to their relatively late age of initiating sex and generally low number of partners.

Public policy debate concerning teenage pregnancy centers upon the alternatives of primary prevention (reducing risk exposure by delaying the onset of sexual activity) versus secondary prevention (reducing the impact of exposure by increasing effective contraception among the sexually active). The gains that can be achieved through primary prevention are greatest for groups with high exposure, i.e., those who initiate sexual intercourse early—non-Hispanic Whites and US-born Mexican Americans. Relative to these groups, Mexico-born Mexican Americans delay the onset of sexual activity considerably, but nonetheless experience high fertility. Conversely, the gains that can be achieved through secondary prevention are greatest for groups with high rates of pregnancy among the sexually active. Although such pregnancy rates are high for all three ethnic groups, the most vulnerable are the two Mexican American groups—the Mexico-born for all pregnancies and the US-born for nonmarital pregnancies. Effective primary or secondary interventions would serve to diminish early fertility across ethnic groups. Our results suggest, however, that the potential reduction in early births that can be realized at various junctures in the sequence of fertility-related events may differ by ethnicity.

The timing of such interventions is critical. Common wisdom asserts that prevention should commence early, a recommendation supported by the early onset of sexual activity documented here. The high hazard rates during the middle to late teen years, however, indicate that prevention activities should continue throughout the adolescent years. Moreover, given the accelerating pattern of sexual activity with increasing age, the focus of prevention activities should shift over time toward a greater concentration on secondary prevention. Also, such prevention activities need to incorporate consideration of marital as well as nonmarital contraception. Programs that focus solely on preventing nonmarital sexual relations leave young women unprepared for reproductive decisions within marriage.

Finally, public policy and funding decisions pertaining to abortion are likely to impact most upon non-Hispanic White adolescents. While young women in all three ethnic groups terminate pregnancies, non-Hispanic Whites are most likely to resolve pregnancies with abortions. Reduction in the availability of abortion, particularly to juveniles, is therefore likely to increase births sharply among young non-Hispanic Whites, but to have comparatively little impact among young Mexican Americans.

Prior Condom Use and the Risk of Tubal Pregnancy

De-Kun Li, MD, MPH, Janet R. Daling, PhD, Andy S. Stergachis, PhD, Joe Chu, MD, MPH, and Noel S. Weiss, MD, DrPH

Abstract: The relationship between prior condom use and tubal pregnancy was assessed in a population-based case-control study at Group Health Cooperative of Puget Sound during 1981–86. We interviewed 227 women with a tubal pregnancy who had no clinical indication of infertility and no history of sterilization and 674 similarly defined controls who were matched to the cases on age and county of residence. A history of condom use for more than one year was associated with a decreased risk of subsequent tubal pregnancy (RR = 0.74, 95% CI = 0.44, 1.26) adjusted for the effects of age, current use of contraceptive methods, educational level, and age at first intercourse. The effect was more pronounced when condoms had been used during five-year periods with more than one partner (RR = 0.38, 95% CI = 0.15, 1.0) than during five-year periods with one partner (RR = 0.89, 95% CI = 0.45, 1.76). Condom use for less than one year was unrelated to risk of ectopic pregnancy. Since the use of condoms offers protection against sexually transmitted diseases, one or more of which are likely to be causally related to tubal pregnancy, the observed negative association plausibly represents a protective influence of long-term condom use on the occurrence of tubal pregnancy. (*Am J Public Health* 1990; 80:964-966.)

Introduction

Some sexually transmitted diseases (STDs) are now considered to be major risk factors for tubal pregnancy,[1] and condom use is believed to be protective against sexually transmitted diseases,[2] so condom use should protect women against tubal pregnancy. Nevertheless, direct evidence to support this inference is lacking. We therefore analyzed data gathered in a population-based case-control study to assess whether condom use is associated with a reduced risk of subsequent tubal pregnancy.

Methods

Details of the study methods can be found elsewhere.[3] Briefly, all subjects in this study were members of the Group Health Cooperative (GHC), a health maintenance organization in the Puget Sound area of Washington State. We identified 396 newly diagnosed cases of ectopic pregnancy through a computerized hospital discharge system between October 1981 and September 1986. After 11 (2.8 percent) refusals for participation from patients' physicians, 39 (9.8 percent) refusals from patients themselves, and nine (2.3 percent) lost to follow-up, 337 (85.1 percent) cases participated in the study.

Controls were randomly selected from the GHC membership file from the calendar quarter of the diagnosis of the tubal pregnancy, and were matched to cases on age and county of residence. In order to be eligible for participation in the study, controls had to be at risk of conceiving and being diagnosed with a tubal pregnancy, i.e., sexually active within 12 months prior to the time of being selected; without a male sexual partner(s) who was known to be sterile; and not pregnant, or less than four months pregnant, at the time selected. Of 1,139 controls initially chosen, 32 (2.8 percent) were not available for the study due to their physicians' refusal, 168 (14.7 percent) refused to participate, 46 (4.0 percent) were lost to follow-up. A total of 893 (78.4 percent) control subjects agreed to participate in the study.

A structured personal interview was conducted with each subject to obtain information on demographic characteristics, reproductive history, contraceptive experience, and medical history. Women were asked not only the total number of sexual partner(s) and the age of first intercourse, but also the number of sexual partners during specific intervals: less than 16 years of age, ages 16–20, 21–25, 26–30, 31–35, and 36–40. Details of life-time contraceptive practices included the types of contraceptive methods used, brand (if applicable), starting and ending dates, and the reasons for stopping contraception.

In order to make case and control groups comparable with respect to their opportunity for exposure (i.e., duration of condom use), women with characteristics likely to be related independently to the occurrences of tubal pregnancy—a history of previous sterilization or previous infertility tests—were excluded from the analysis. Furthermore, those with a prior ectopic pregnancy and those whose ectopic pregnancy was not in the fallopian tube were also excluded, leaving 227 cases and 674 controls available for analysis. A "reference date" was established for each subject—the estimated date of conception for cases and the mid-point of that same quarter for controls—and only exposures at and prior to that time were ascertained.

To determine if the association of condom use and tubal pregnancy varied with subject's sexual behavior, the relation was evaluated separately for those five-year periods during which there had or had not been more than one sexual partner.

The odds ratio, accompanied by its 95% confidence interval, was used as an estimate of relative risk. Logistic regression analysis was employed to adjust for potential confounders.[4]

Results

Table 1 presents some characteristics of the study subjects. Age remained comparable between case and control groups after the exclusions made in this study. Compared to controls, cases were more likely to have been married (or living as married) at the date of diagnosis of the tubal pregnancy, to be Black, and to have had less education.

Cases were more likely than controls to have had a greater total number of sexual partners, to have become

sexually active at an earlier age, and to have had a history of infection with gonorrhea (Table 1). Cases were far less likely than controls to have been using any kind of contraceptive method at the reference date, although use of the intrauterine device (IUD) at that time was comparable between the two groups (Table 1).

The relation between duration of condom use and tubal pregnancy is shown in Table 2. Condom use was associated with a decreased risk of a subsequent occurrence of tubal pregnancy only when it had been used for a relatively long time (i.e., more than one year). After taking into account her age, current contraceptive use, educational level, and age at first intercourse, a woman whose partners used condoms for more than one year during any five-year period in which she had more than one sexual partner had only 38 percent of the risk for subsequent occurrence of tubal pregnancy compared to never-users (95% CI = 0.15, 1.0). Condom use restricted to periods in which the woman had only one sexual partner was not associated with a decreased risk of tubal pregnancy, nor was condom use for less than one year, irrespective of the number of partners. Further adjustment for the following variables did not influence the results: number of life-time sexual partners, history of gonorrhea infection, oral contraceptive and IUD use, reproductive history including gravidity, parity, spontaneous and induced abortion, religious briefs, smoking habits, the year of diagnosis of ectopic pregnancy, family income, and race. The number of five-year intervals in which more than one partner had been present was similar between case and control women, and so this did not produce differences in the size of the association with condom use.

Discussion

Our finding of a negative association between prior condom use and the occurrence of tubal pregnancy might have been anticipated, given that condom use can reduce the risk of transmission of many forms of sexually transmitted diseases, some of which are important etiologic factors for tubal pregnancy. Nonetheless, it is necessary to keep in mind several limitations of our study when interpreting these results. First, our ability to assess exposure to sexually transmitted diseases themselves was extremely limited. We were able to measure only a distant correlate of such exposure—the presence of more than one sexual partner during various periods of a woman's reproductive life. Thus, our finding of a reduced risk of tubal pregnancy associated with condom use restricted to women whose partner's use occurred during periods of her life in which she had more than one partner could be a reflection of yet a far greater protective effect of condom use among women who truly had been exposed to one or more sexually transmitted diseases. On the other hand, we made numerous comparisons in this data set, and the restriction of a negative association to this subgroup of women could have been simply the result of chance.

Second, the control group of women chosen in this study—women capable of becoming pregnant—had certain disadvantages in examining the influence of prior condom use. The use of the particular control group was dictated by our interest in studying the influence of exposures at the time of conception (e.g., IUD use), plus our concern that the commonly used alternative group (women completing an intrauterine pregnancy) provided a substantial opportunity for bias,[5] since a sizable portion of women who conceive a pregnancy do not go on to deliver it. The selection of controls who were believed to be capable of becoming pregnant led to a large case-control difference in the frequency of contraception (of any type, see Table 1) at the reference date. As expected, far fewer cases than controls were attempting to contracept at that time. Nonetheless, since there were sizable numbers of contraceptors and noncontraceptors among both cases and controls, and since we were interested in the effect of condoms on tubal pregnancy above and beyond their ability to prevent pregnancy per se, we were able to adjust for the use of contraception at reference date and thus obtain an unconfounded (with respect to this factor) evaluation of the influence of past condom use.

In our analysis, we sought to address the possibility that the reduced risk among women whose partner(s) had used a condom resulted only from an increased risk associated with use of certain other forms of contraception. First, we restricted the analysis to women who had not been sterilized. Then, we assessed the influence of condom use adjusting for prior use of contraceptive methods that plausibly could affect the occurrence of pelvic infection (and thus tubal pregnancy), i.e., IUDs and oral contraceptives.[1, 6] A negative association between condom use and tubal pregnancy persisted despite such adjustments.

While several studies of tubal pregnancy have examined the influence of barrier methods of contraception in general,[1, 7–10] only our earlier[9] and current studies focused on prior condom use. The earlier study did find a 60 percent reduction in the incidence of tubal pregnancy among women whose partner(s) had used a condom, but neither duration of use nor the further influence of number of partners was analyzed. Although the use of barrier methods in general has been found

[b]Women whose partners used condoms during any five-year period in which there had been more than one sexual partner were excluded.

to be associated with a modest reduction in the risk of tubal pregnancy,[7,8,10] the possibly different impact on tubal pregnancy of individual barrier methods limits the interpretation of the results with respect to any one of the methods. In addition, by studying current users versus current non-users,[8,10] previous studies allowed for the possibility that the low risk was due simply to the ability of barrier methods to prevent conception.

In conclusion, after controlling the "need" for contraceptive use, age, current use of contraceptive methods, education level, and age at first intercourse, we found that use of a condom for more than one year reduced the risk of tubal pregnancy. The effect was more pronounced when condom use was during any five-year period in which there had been more than one sexual partner. This observed negative association may plausibly represent a protective effect of long term use of condom on the occurrence of tubal pregnancy through the prevention of one or more sexually transmitted diseases.

Age and Human Immunodeficiency Virus Infection in Persons with Hemophilia in California

ROBERT C. HOLMAN, MS, EDWARD D. GOMPERTS, MD, JANINE M. JASON, MD, CHARLES F. ABILDGAARD, MD, MICHAEL T. ZELASKY, BS, AND BRUCE L. EVATT, MD

Abstract: Thirteen hemophilia centers provide comprehensive care to approximately 90 percent of persons with hemophilia in California. For 1987, these centers reported patient human immunodeficiency virus (HIV) antibody status, age group, level of clotting factor deficiency, and hemophilia type on 1,438 persons with hemophilia A and B; HIV serologic status was known for 860 persons (59.8 percent) of whom 537 (62.4 percent) were HIV-antibody-positive. The HIV positivity rate increased with age after taking into account hemophilia type, clotting factor level and treatment center type. The three-year cumulative incidence of reported AIDS (acquired immunodeficiency syndrome) cases based on the number of HIV positive patients, was 11.6 percent. The cumulative incidence rate was 14.6 percent (54 of 370) for those patients over 20 years of age and 4.8 percent (8 of 167) for those under 21 years of age. Although a comparable distribution of the date of diagnoses of AIDS was seen by age group, there appeared to be a bimodal distribution in the rate of AIDS among the age groups, with the 6–12-year-olds and the 21 and older age groups showing higher incidence rates. (*Am J Public Health* 1990; 80:967–969.)

Introduction

Acquired immunodeficiency syndrome (AIDS) was first documented in persons with hemophilia early in the course of the AIDS epidemic in the United States.[1] Studies of stored serum specimens showed that a high percentage of hemophilic persons became infected with human immunodeficiency virus (HIV) over a relatively short time. Most patients became infected between 1981 and 1984; the peak incidence of infection occurred in 1982 and 1983.[2,3] The reasons for the quick spread of infection in this population were the widespread use of commercial clotting factor concentrates prepared from pools of sera collected from between 2,000 to 20,000 donors[4] and the widening prevalence of this infection in the United States, and therefore in the donor population, before HIV blood screening practices were in effect.

The Centers for Disease Control (CDC) collects data characterizing AIDS in the United States hemophilic population through state health departments.[5,6] This reporting mechanism has been exceptionally efficient, with at least 97 percent of the cases reported.[5]

The duration of HIV infection before the onset of AIDS varies from as short as a few months to an as yet indeterminate number of years, with a median of nearly 10 years.[7] However, the duration or latency period to AIDS in persons with hemophilia may differ from that of other AIDS risk groups.[8–10] The most important factor in disease progression is time from primary infection, but factors as diverse as geographic location[11] and HLA (human lymphocyte antigen) type[12] may play a role. In this study, the HIV seroprevalence and incidence of AIDS in hemophilic persons in California were estimated to assess associations with age, hemophilia type, and clotting factor level.

Methods

Five federally funded California hemophilia centers (FFC) provide comprehensive care to approximately 65 percent of the persons with hemophilia A and B in California[13] and report activities annually to the federally funded agency. An additional 25 percent of the patients receive care through eight other centers (SSC) and report voluntarily. It is estimated that the remaining 10 percent of the patients receive care through health maintenance programs, the military, or private practitioners. As part of their 1987 annual report, both groups of centers were asked to include additional information for all hemophilia patients on HIV antibody test result (positive, negative, or not tested); age group of patient (<5 years, 6 to 12 years, 13 to 16 years, 17 to 20 years, or above 20 years); level of clotting factor deficiency (<5 percent or 5 percent–40 percent); and type of hemophilia (Factor VIII or Factor IX deficiency). The HIV antibody testing of hemophilia persons is voluntary, with encouragement to all patients. Mild hemophilia persons were usually followed less actively at the centers, and centers were less aggressive about testing younger children since they were much less likely to be infected because viral-activated products had usually been used.

For this study, AIDS cases were those reported to CDC as of 9/2/88 by any center, physician, and local department of health within California, that were diagnosed between 1/1/85 and 12/31/87, and were verified by the reporting official to have received their care from one of the 13 reporting centers. The inclusive time period of 1985–87 was used because use of viral inactivated products was instituted in 1984, and seroconversion had virtually ceased by 1985.[14] Thus the number of seropositive persons was stable for this period and the cumulative incidence of AIDS is the number of reported AIDS cases divided by the number of known HIV seropositive patients during the inclusive three-year period of 1985–87. The age group of AIDS cases is based on age as of 1987, the year of the annual report. Similar analyses were repeated when California hemophilia-associated AIDS cases included those not reported by FFCs or SSCs.

Logistic regression analysis was used for both the univariate and multivariate analyses to calculate odds ratios (OR) and 95 percent confidence intervals (CI).[15,16] Univariate analyses were performed on each of the four categorical variables (age group, hemophilia type, clotting factor level, and treatment center type). Next, for HIV-tested patients, a multivariate analysis was used to analyze the four variables in a full model to adjust for the effects of potential confound-

ing variables. Logistic regression analysis was also used to compare between the HIV-positive patients in relation to outcome of AIDS. For this analysis, the three categorical variables were age group (≤20 and ≥21 years of age), hemophilia type, and clotting factor level.

Results

Most patients (72.0 percent) were reported from the five major centers which also tested proportionally more patients (Table 1). Clotting factor levels <5 percent and age were also associated with testing, but factor deficiency was not associated.

Of the 860 tested patients, 537 (62.4 percent) were HIV-antibody-positive and 323 (37.6 percent) were antibody-negative. The odds ratio of HIV seropositivity increased with age group (Table 2). The odds of HIV seropositivity may have stabilized beginning with the 13–16-year age group: ORs of the 13–16 and 17–20 year-old age groups did not differ from those 21 years of age or older (OR = 1.3, CI = [0.7–2.4]; OR = 1.5, CI = [0.9–2.7], respectively). Factor VIII deficient patients were more likely to be HIV positive than factor IX deficient patients, and patients with clotting factor levels <5 percent were more likely to be HIV positive than patients with clotting factor levels ≥5 percent. Using a full logistic model, there were no differences in HIV positive rates in patients from the two groups of centers; the differences in HIV positive rates by age, hemophilia type, and clotting level remained.

Sixty-two patients from the hemophilia reporting centers were reported with an AIDS diagnosis made in 1985–87 in California. This represented 11.6 percent of known seropositive patients in the centers. Age was the only factor associated with AIDS diagnosis (Table 3). Eight of 167 of those less than 21 years old developed AIDS, six persons 6–12 and 2 persons 17–20. Distribution of the date of diagnosis for the eight persons <21 years of age was similar to that of the older population. However, a difference in the rate of AIDS was seen between age groups. This distribution was bimodal with the 6–12-year-old group showing higher rate (10.0 percent) than those in the 13–16 and 17–20 age groups (0.0 percent and 3.2 percent, respectively), although not as high as the ≥21 age group. Results similar to those described above were also seen in the analysis of all 72 patients who were reported by the centers as developing AIDS through 1987.

Discussion

Most persons with hemophilia became infected with HIV in 1981 to 1984.[2,3] After 1984, viral-attenuated clotting factor concentrates became widely used resulting in only rare seroconversions in uninfected persons.[17] Therefore, a low seroprevalence in hemophilic children under 6 years of age and an increasingly higher prevalence in older persons with hemophilia was to be expected.[18] In addition, we found this association to remain when taking into account the hemophilia type, clotting factor level, and treatment center type. We also found that older persons with hemophilia were at a higher risk of AIDS, as was shown in a recent study.[19] Although patients between 6 and 12 years had a higher rate than those of other age groups <21 years, there was a small number of cases in each of those age groups.

Why patients followed by one set of centers were more likely to be tested than patients from the other set is not

known. The eight hemophilia programs with a lower testing rate were usually staffed by health care workers providing care to patients with a variety of hematologic and oncologic diseases, whereas the five centers with a higher testing rate were more hemophilia focused.[13]

In this retrospective study, the denominator of HIV seropositive persons shifted over part of this period, with the prevalence of infection increasing during 1981 through 1984. Although this might affect our results, the substantial differences observed suggest that these estimates, which cannot be better specified, are not likely to account for the observed differences. Also, as expected, the tested group consisted of patients that were older and/or with severe hemophilia, both of these factors would tend to bias the associations with HIV seropositivity toward nonsignificance. That is, the patients not tested were younger and probably at a lower risk of infection; therefore, if tested, the seropositivity rate of younger patients would be lower and the observed difference detected in age may be even greater than noted by our estimates. The analysis of the rate of AIDS was performed using AIDS cases from the defined centers as the numerator and patients with a positive HIV antibody status determined from those tested as the denominator. Thus, the age bias in HIV testing would only tend to underestimate the denominator for younger persons. The observed age difference of the rate of AIDS may thus be more dramatic than estimated herein.

The reason for the discrepancy in AIDS prevalence between age groups may be that younger hemophilic patients received less clotting factor than older hemophilic patients, that is, they were exposed to the HIV virus later than their older counterparts and have an "earlier" phase of the infection. Although it cannot be proved or disproved by this study, because specific dates of seroconversion are not available on these patients, this hypothesis is unlikely. The critical variable in hemophilia treatment may be the frequency of infusions and extent of exposure to different clotting factor concentrate lots, not age. Persons bleeding more frequently will be exposed to more lots of commercially prepared clotting factor concentrates and therefore be more likely to receive concentrates from a contaminated lot. Young, active hemophilic boys ages 3 or 4 years through adolescence are the most physically active and consequently have frequent hemorrhages requiring infusion therapy.[20] However, the rate of AIDS would be expected to be high through adolescence, not just for the 6- to 12-year olds age group. While exceptions certainly occur, the size of the currently reported population would result in a relatively homogeneous group. Further, the epidemiologic curves of AIDS diagnosis over time for those <21 and ≥21 years are similar. Consequently, reasons for the differences in the biological response to HIV infection between the two broad age groups should be sought among physiologic mechanisms. In addition, if age differences were representative of the true differences in the population, and age is an important cofactor in the development of AIDS, the important scientific and public health implications merit further investigation.

The Infrastructure of Religious Communities: A Neglected Resource for Care of People with AIDS

EARL E. SHELP, PHD, EDWIN R. DUBOSE, PHD, AND RONALD H. SUNDERLAND, EDD

Abstract: The AIDS Interfaith Council of Houston, sponsored by the Foundation for Interfaith Research and Ministry, recruits, trains, and coordinates volunteers for home-based care for adults and children with AIDS (acquired immunodeficiency syndrome). The program provides compassionate, non-judgmental care for the sick and respite support for the primary care provider. Care is provided by highly motivated, trained volunteers. The respite care team model also represents a support system to complement medical management and other health care services for people with AIDS. With the expanding number of cases and the growing preference for clients to remain at home, such a model will become increasingly important as people continue to live longer with AIDS. (*Am J Public Health* 1990; 80:970–972.)

Introduction

With the advent of acquired immunodeficiency syndrome (AIDS), biomedical scientists, physicians, providers of social services, and social communities face a complex and serious challenge. Progress has been made in understanding the etiologic virus—human immunodeficiency virus (HIV)—its destructive effect on a human host, and palliative therapies for HIV infection. Improved medical management of associated illnesses has been developed. Given the psychosocial, emotional, medical, and economic burdens related to HIV disease, the importance of supportive services is clear.[1,2] Traditionally, in times of illness, religious communities have been an effective support system for individuals, their families, and friends. In the AIDS epidemic, these communities are challenged to respond to the sick and suffering with compassionate, non-judgmental support.

The Houston (Texas) Standard Metropolitan Statistical Area presently ranks fourth among cities in the United States for cumulative reported cases of AIDS.[3] As of January 2, 1990, the cumulative case report for people diagnosed with AIDS was 3,558, of whom 1,177 are living.* It is projected that the cumulative number of reported AIDS patients in Houston alive at the end of 1992 will range from 4,573 to 5,740.**

Relatives and friends of people with AIDS face the pressures of caring for people who are seriously ill as well as dealing with the economic and psychosocial concerns that accompany AIDS. Outpatient and home-based care are important for both economic and emotional reasons.[4,5] Along with the deterioration of their health and the fear of abandonment, patients and caretakers must cope with loss of employment and insurance. Also, an increasing number of people with AIDS have no insurance at the beginning of their illness. If the rate of progression and the preferences of people with AIDS for outpatient and in-home terminal care remain constant, the need for volunteers to provide in-home respite and supportive care will grow. In this article we describe an innovative service project which addresses the needs of people living with AIDS. A detailed description of the program, including the content and process of the educational program for the volunteers, is available from the authors.

The AIDS Interfaith Council

The AIDS Interfaith Council of Houston is an association of clergy and laity which provides educational and service programs in response to the expanding AIDS epidemic. A program sponsored by the Foundation for Interfaith Research and Ministry, the Council was created in January 1986 to offer congregation-based supportive care to people with AIDS and their loved ones. Over 650 volunteers organized in congregation-based teams offer friendship and respite from some of the time consuming tasks involved in caring for a person who has become seriously ill. The paid staff of the Foundation, which coordinates the activities of the Council, presently consists of 10 people who are responsible for administrative, supervisory, educational, training, service, resource development, fund raising, and counseling duties.

The AIDS Interfaith Council appears to be the oldest, largest, and most active congregation-based supportive program in the United States. Surgeon General C. Everett Koop noted during a speech to the Council in May 1988, "I think that what you've done here is tremendous . . . you're way ahead of the rest of the country. If it would be possible to take what you've done to other parts of the country, we would see networks such as you have here spring up all over the land."[6]

Program Description

The respite care teams are the heart of the program. Teams of volunteers from individual congregations are recruited and trained to provide social support, physical care, emotional support, and spiritual care to dependent, home-based patients and their loved ones. At the end of 1989, 28 Houston area churches and synagogues each provide a team of volunteers sponsored, trained, and coordinated by the AIDS Interfaith Council. No fees are charged for any services of the Council or the care teams.

Volunteers are recruited during educational programs in congregations at which facts regarding AIDS and risk reduction are given. Recruiters remind people who attend that they have a religiously grounded moral obligation to care for sick and dependent people regardless of the affliction or the means by which the dependency developed.[7] Education becomes an essential prerequisite to the recruitment of volunteer teams, since it is during these sessions that AIDS-related myths and fears are addressed.

Once recruited, teams of at least 14 people receive three types of training for their services to people living with AIDS. One component focuses on organizational and operational matters. A second component is on the development of listening and care skills, including how to provide emotional support to sick and dying people. A third component deals with basic nursing and hospice care of people with AIDS. The three components require seven hours of orientation and training. The team chooses a team leader who assumes overall administrative responsibilities for scheduling, communication, and record-keeping. The teams schedule monthly meetings for discussion of patient progress, continuing education, peer support, and social support.

Teams then are assigned patients who are either self-referred or have been referred to the Council by physicians, social workers, discharge planners, and other service agencies. Ordinarily, paired team members meet with each patient at a frequency per week agreed upon by the client and caretaker and consistent with the person's needs. Visits usually last between three and four hours. As a client or caretaker desires, e.g., during a crisis period, additional team members are assigned. By the time a client progresses to a terminal state, services typically are provided seven times a week. If a client enters hospital for acute or terminal care, the team maintains contact until discharge to home or death. Team members know, as they accept responsibility for the care of a new client, that they may expect to share in his or her death.

This commitment enables the person with AIDS to retain a degree of autonomy and independence that otherwise would be difficult to maintain. Depending upon the person's needs and desires, the teams provide social and emotional support, accompany the client on shopping activities, and provide housekeeping assistance, transportation, basic nursing care, and other appropriate "hands-on" care. Care team members encourage clients to set their own agendas, thereby reinforcing their autonomy. Their readiness to help a client sift through options and explore possible actions, to "listen" as the person works through his or her emotional concerns, together with offers of practical aid, affirm the client's dignity.[8] Pastoral care and sacramental ministries are available upon request by the client. No spiritual or moral agenda is forwarded by any team member.

The focus of care and support is not restricted to the person with AIDS. Other people in the home (roommate, lover, family member) often welcome the respite and emotional support provided by team members. Primary care providers are supplemented, not replaced, by these teams. Strong bonds tend to be established over time. Survivors of deceased loved ones often become involved in this program in gratitude for the care received and to continue their commitment to people touched by AIDS.

We have learned that people in the advanced stages of HIV infection have in-home needs that tend to be too great for one or two people to provide. The availability of 14–20 people to supplement or to provide primary supportive care tends not only to improve the quality of life for a dependent client, but also appears to be a means for caring for people at home rather than in a higher cost institution. The presence of volunteers also allows people who so desire to die at home. Without this sort of support, many indigent and non-indigent people would spend their last weeks in hospital or nursing home (if the nursing home would accept a person with AIDS) against their wishes and at a higher expense to them or the community.

The nature of the activities and context in which teams are involved creates stress, grief, and bereavement which must be addressed to maintain the volunteers' emotional well-being and the quality of services. Supervision of team activities and group therapy for teams, therefore, are crucial. Each team meets with supervisory/therapeutic personnel (MSW or doctoral level professionals) approximately every 4–8 weeks. At these meetings, individual and team concerns are addressed. Guidance and intervention by supervisory or therapeutic personnel occurs as indicated. The volunteer commitment and congregational endorsement of the teams, plus careful supervision, appear to minimize volunteer turnover.

TABLE 1—Trends in Volunteer Services by Client Breakdown, AIDS Interfaith Council of Houston

	1986	1987	1988	1989	Total
Number of Teams (cumulative per year)	6	11	21	28	28

*No record of client contact hours was kept in 1986 or 1987.
**Estimated number of reported new cases per year, Harris County Health Department, December, 1988.

Activity Statistics

The program has served 16 percent of the cumulative AIDS cases in the Houston SMSA since the Council began in 1986 (486 of 3,005 cases diagnosed). There has been an increase in the number of teams in each year of the program. The number of people with AIDS who have made use of the care teams also has grown every year since 1986 (Table 1). The growth in the provision of volunteer services clearly outdistances the rate of growth of the epidemic in Houston. The rate of increase in clients doubles the rate of increase of new diagnoses in Houston in 1988 and 1989 (Table 1). Over 73,000 contact hours of service were given in 1988–89. At a value of $8/hour for comparable home attendant care,*** volunteers provided $584,000 worth of services during the two years.

Discussion

The value of the program is clear. The program seems to be a logistically efficient means of providing home-based care for people touched by AIDS. By recruiting volunteers from religious communities, the program draws upon a ready pool of motivated people already oriented to visiting the sick. The team model provides peer and supervisory personnel to resolve volunteer and client problems.

The adult care team model has the capacity for replication in any neighborhood and is being duplicated in other cities (e.g., New Orleans, Baton Rouge, San Antonio, Little Rock, Albu-

***According to the Visiting Nurses' Association, the value of home attendant care in the Houston area is $8/hour.

querque, and Dallas-Ft. Worth).† Finally, given the widespread misunderstanding of HIV/AIDS in the general public, the program encourages a greater degree of knowledge and compassion for affected people. As more congregations become involved, a discrediting of stereotypes about people with AIDS occurs. The work of the Care Teams becomes a form of community education both within the general community about HIV/AIDS and for at-risk people about the perceived indifference to their condition by the general population.

The care team model has encountered several problems. First, since the medical knowledge and treatment of AIDS changes rapidly, there is a need for continuing education of volunteers. Volunteers are open to continuing education only if the programs are conducted in the setting of the team's regular monthly meeting. Traveling to 28 locations for continuing education sessions makes for inefficient use of staff time, but elicits a higher response from volunteers. Second, nearly all clients are followed to death. As volunteers become increasingly involved in the lives of their clients, the issues of grief and bereavement are very real. Therefore, both individual and group supervision of the volunteers are important aspects of the program. Therapy is made available at no charge to the volunteers who request it.

We have found if difficult to develop a volunteer profile. It is our impression that the teams generally reflect the demographic profile of their congregations. However, our experience has been that volunteers would interpret questions regarding their personal lives as intrusive and irrelevant to their service. Their priority clearly is patient care, no participation in record-keeping.

The 1989 rate of increase in new Council clients moderates an upward trend but continues to outpace the increase in new diagnoses. The clients on average are receiving care for a longer period of time, thus reducing the number of new clients a team can serve during the year (Table 1). The number of referrals and requests for service increased in 1989. All requests could not be met, however, because clients resided in areas in which presently there is little or no team coverage.

Therefore, a fourth area of concern is the resistance of congregation leadership to an identification with AIDS and those people affected by it. Resistance to educational programs among some religious groups ranges from specific concerns about condom use, drug use, and sexuality in general. Some religious leaders seem to fear that discussion of HIV/AIDS is equivalent to promoting of high-risk behaviors. The Council maintains that objective information about HIV/AIDS is a primary means for containing the disease. Combined with a sensitive concern for the moral and theological positions of the various communities, knowledge about HIV disease lessens personal anxieties and fears and helps build community support.

Fifth, as in the rest of the country, there is an increasing number of IVDUs (intravenous drug users) with AIDS in Houston. Studies show that minority populations are disproportionately represented in the AIDS epidemic.[9,10] This development highlights the need of involving Black and Hispanic churches in the Council's work. There has been some recent success in recruiting teams from several Black churches. Outreach to Hispanic groups has become a priority. Nevertheless, given the large number of Black and Hispanic congregations in Houston, response has been disappointing. Cultural factors such as the stigma of homosexuality play a role, as does the reluctance to link AIDS closely to minority communities. Until religious leadership in all areas of Houston recognize the need to respond to the AIDS crisis, the availability of congregation-based care team services to minorities will be limited.

Finally, with the increasing rate of HIV infection among female IVDUs or the sexual partners of IVDUs, the number of pediatric AIDS cases is increasing in Houston. Presently, the care teams are expanding their services to include children and their families. The needs of families with HIV seropositive children are different than those of adults.[11,12] Special features associated with these needs include infection in one or both parents, perhaps a single parent family setting, as well as the possible presence of siblings. Building upon experience gained in the last four years, the Care Team model has been revised to provide services to these families. Beginning in July 1989, the Foundation committed its resources to recruiting, training, and supervising Pediatric Care Teams. A four-hour training program oriented toward the features of pediatric AIDS was added to the adult training component. Eight of the 28 care teams are working with children who have AIDS. Since July 1989, these volunteers have extended care to 15 children, of which two have died.

The problems and concerns of men, women, and children living with AIDS are many and severe. As the numbers of people with HIV disease increase, the demand for medical and support services will continue to grow. One resource that can be developed and utilized to ease the psychosocial burdens of people with AIDS is the congregation-based care team model.

†Based upon the work of the AIDS Interfaith Council's Adult AIDS Care Team model, the staff of the Foundation participated in writing the proposal for the creation of a regional interfaith project including the cities of New Orleans, Baton Rouge, San Antonio, Little Rock, and Albuquerque. This proposal was funded by the Robert Wood Johnson Foundation in 1988. Dallas-Ft. Worth has followed a similar course with funding from Robert Wood Johnson Foundation.

ACKNOWLEDGMENTS

The authors would like to acknowledge the Texas Department of Health for its generous support of the Adult Care Team program. Also, we are grateful to the Moody Foundation, Hermann Hospital, Northwoods Presbyterian Church, Memorial Drive Presbyterian Church, and St. Luke's United Methodist Church for their support of the Pediatrics Care Team program.

Maintenance of Safer Sexual Behaviors and Predictors of Risky Sex: The San Francisco Men's Health Study

MARIA L. EKSTRAND, PHD, AND THOMAS J. COATES, PHD

Abstract: This paper describes the sexual behavior changes made by 686 gay and bisexual men in San Francisco between 1984 and 1988, focusing on the individual maintenance of this behavior change over time. There were drastic reductions in insertive and receptive unprotective anal intercourse over time and the vast majority of subjects were able to maintain these changes for at least 12 months prior to the last interview. A total of 12 percent of participants admitted to relapsing to unprotected receptive anal intercourse following initial behavior change; 10 percent reported engaging in unprotected receptive anal sex during every year of the study period. Men were more likely to practice unprotected anal intercourse in 1988 if at baseline they were younger, practiced unprotected anal intercourse, reported more sex partners, did not have a close friend or lover with AIDS, and engaged in fewer other health-related behaviors. (*Am J Public Health* 1990; 80:973–977.)

Introduction

This study seeks to document the stability of change and psychosocial predictors of unprotected anal intercourse in a probability sample of San Francisco gay and bisexual men. Gay men account for 95.7 percent of all AIDS (acquired immunodeficiency syndrome) cases in San Francisco to date[1] and 68 percent of the cases in the United States to date.[2] San Francisco gay and bisexual men have been particularly hard hit by this epidemic with infection rates estimated at 52 percent.[3]

Earlier studies [3–5, *, **] have documented drastic sexual behavior changes in volunteer samples of gay and bisexual men in San Francisco. Although these findings are encouraging, it is crucial that the changes are maintained over time. There have been few studies examining the long term stability of this behavior change. Joseph, Montgomery, Kessler, *et al*,*** reported that between 25 and 35 percent of their sample of Chicago gay men resumed high-risk behavior at least once following initial risk reduction. In Boston, 13 percent of the gay men who reported practicing safe sex in year one relapsed during the following year.† The present study examines both the prevalence and decline of high-risk behavior among all gay and bisexual subjects as well as the stability of this change and the relation between high-risk behavior and demographic and psychosocial variables, HIV (human immunodeficiency virus) antibody status, HIV-related symptoms, and other health-related behaviors.

Methods

Subjects

The San Francisco Men's Health Study is a prospective study of single, predominately White, well-educated males between the ages of 25 and 54 recruited by multistage probability sampling from the six kilometer square area in San Francisco with the highest cumulative incidence of AIDS in 1984. Sampling methods, as well as statistical, and data collection procedures have been described previously.[3,5,6]

The analyses in the present study include data on 686 gay and bisexual men who participated in the first year (July 1984–June 1985) of data collection, 633 who participated in the second year (July 1985–June 1986), 627 from year three (July 1986–June 1987), and 592 from year four (July 1987–June 1988). At least 57 subjects died between July 1984 and June 1988 and an additional 25 subjects had died from 1988 to 1989.

Demographic subject characteristics for this subsample, obtained in July 1984, show that this area is populated mostly by White, employed, and well-educated gay males.

Analysis of Attrition Bias

We compared those subjects who remained in the study to those who dropped out between 1984 and 1988. The scores of these two groups on all predictor and outcome variables in year one did not differ appreciably with regard to sexual behaviors (Table 1). Dropout subjects were more likely to be HIV positive in year one, and to report HIV-related symptoms at that time; they were more depressed, drank less alcohol, and thought of themselves as gay at an earlier age than subjects who remained in the study. These differences probably reflect the differing percentages of HIV positive subjects in the two groups.

Measures

Sexual Behavior—Self-report data on high-risk sexual behavior were obtained eight times from July 1984 to June 1988. Subjects were asked whether they had engaged in any sexual activity during the previous six months. Those who answered "yes" were then asked whether they had engaged in any of 22 specific behaviors. For each of these activities, the subjects were asked to report the number of partners with whom they had engaged in that behavior since the last clinic

		2. means	
Age (years)	36.5	36.5	(−1.5,1.4)
Age (years) at which first thought of self as gay	18.9	17.4	(−3.0,−.1)
Age (years) at which first socialized as gay	21.4	20.6	(−1.7,.2)
Alcohol consumption (mean)	4.3	3.8	(−.8,−.1)
Loneliness (mean)	4.3	4.0	(−.1,.7)
Depression (mean)	8.7	11.1	(.5,4.3)
Amount of social support (mean)	81.2	89.9	(−1.0,.6)
Social support satisfaction (mean)	32.1	32.3	(−7.4,24.6)

visit. Although unprotected insertive and receptive anal intercourse and multiple sexual partners are the only firmly established major risk factors for seroconversion in male-to-male relationships,[7] we also examined the prevalence of anal-oral contact, genital-oral contact, fist-anal contact, and whether the respondent had engaged in sex with anonymous partners. To facilitate presentation, we combined these eight six-month segments into four one-year intervals. Since all of the sexual behaviors have been dichotomized, an affirmative response during either six-month segment in a given year resulted in an individual being classified as having engaged in the behavior during that year.

To examine correlates of risky sex, two multiple logistic analyses were conducted, predicting unprotected receptive and insertive anal intercourse in waves two (January to June 1985) and eight (January to June 1988). The predictor variables in these analyses (Tables 2 and 3) also included items developed for the psychosocial component of the project and were administered to the subjects in wave 2 (January to June 1985); they are defined in detail in the Appendix.

Procedure

We examined yearly prevalence rates of sexual behaviors for the entire gay and bisexual sample. Group changes in sexual behaviors from 1984 to 1988 were then analyzed using McNemar tests.[8]

We also examined fluctuations in individual behavior patterns. In order to do this, the study period was divided into four 12-month segments consisting of: 1) July 1984 to July 1985; 2) July 1985 to July 1986; 3) July 1986 to July 1987; and 4) July 1987 to July 1988. A subject was considered "high risk" for a given period if he reported engaging in any unprotected receptive or insertive anal intercourse with or without ejaculation during that time. This yielded 16 behavior patterns which were combined into four groups; stable low risk, stable high risk, change from high to low risk, and relapse.

The relation between the predictor variables and unprotected anal sex was examined using multiple logistic regression.[9] A dichotomous score was created classifying subjects as high risk if they reported having engaged in either insertive or receptive unprotected anal intercourse during January to June 1985 and 1988.

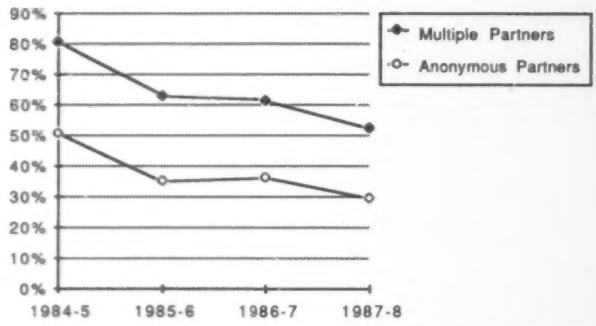

FIGURE 2—Percent Men Who Reported Having Sex with Multiple and Anonymous Partners Each Year

Results

Behavior Change

Figures 1, 2, and 3 present data showing the percent of men who reported engaging in each of the sexual behaviors in years one through four (i.e., 1984–5, 1985–6, 1986–7, and 1987–8). The most dramatic changes have occurred in unprotected insertive (37 percent to 2 percent) and receptive (34 percent to 4 percent) anal intercourse with ejaculation. Significant changes were also reported in insertive and

Predictors	Adjusted Odds Ratio	(95% CI)
Age (20 year difference)	0.6	(0.5,0.8)
Age at which first thought of self as gay	1.0	(0.9,1.2)
Age at which first socialized as gay	1.1	(0.8,1.3)
Number of sex partners	1.4	(1.2,1.6)
Antibody status (positive)	1.3	(1.1,1.5)
HIV-related symptoms	1.1	(0.9,1.3)
Smoking	1.1	(0.9,1.3)
Alcohol consumption	1.3	(1.1,1.6)
Friends, lover with AIDS	0.9	(0.8,1.1)
Loneliness	1.0	(0.9,1.1)
Amount of social support	1.0	(1.0,1.0)
Social support satisfaction	1.0	(0.9,1.2)
Depression	0.9	(0.8,1.0)

receptive anal practices with and without ejaculation, which decreased from 42 percent and 63 percent to 17 and 17 percent respectively. All behaviors changed significantly from year one to year two. After June 1986, most behavior changes leveled off. Unprotected insertive and receptive anal intercourse and insertive oral-genital contact continued to decrease significantly from 1985–6 to 1986–7. The percent of subjects reporting unprotected insertive and receptive anal sex, insertive and receptive oral-genital contact, sex with anonymous partners, and multiple sexual partners continued to decline until 1987–8.

Maintenance of Behavior Change

Behaviors were remarkably stable: 25 percent and 31 percent of the subjects were classified as stable low risk, and an additional 50 percent and 47 percent fell into the change to low risk category. Only 16 percent and 12 percent of the subjects admitted to relapsing to unprotected insertive and receptive anal sex, respectively, while an additional 10 percent were stable high risk.

Younger men were more likely to engage in unprotected anal intercourse than older men in the sample in both 1985 and 1988. Subjects who reported in 1985 that they had friends or lovers with AIDS were less likely to engage in unprotected anal sex in 1988 than were men who did not have this experience (Table 3).

TABLE 3—Longitudinal Predictors of Unprotected Anal Intercourse in 1988

Predictors	Adjusted Odds Ratio	(95% CI)
Age (20 year difference)	0.6	(0.3,0.9)

Depression	1.1	(0.9,1.3)

See appendix for a description of measures

Men who reported engaging in unprotected anal intercourse in 1985 were likely to report doing so in 1988 than were men who had been practicing safer sex only in 1985.

Participants who were HIV positive in 1985 were more likely to engage in unprotected anal sex at that time. However, knowledge of HIV antibody status in 1987 did not predict sexual behavior in 1988. The presence of HIV-related symptoms did not predict report of high-risk behavior.

Men who reported a greater number of partners in 1985 were far more likely to practice unprotected anal sex in 1988 than were men who had been practicing safer sex only in 1985. Subjects who reported consuming a greater volume of alcohol were more likely to report engaging in high-risk sexual behavior than those who reported less alcohol consumption. This relation held for the cross-sectional analysis in 1985, but did not predict risk behavior longitudinally. Subjects who reported smoking regularly in 1985 were somewhat more likely to engage in unprotected anal sex in 1988.

Men who reported greater levels of depression in 1985 were less likely to report having engaged in unprotected anal sex in that year than subjects who reported fewer depressive symptoms. Participants who reported having a large number of people on whom they could rely for social support were less likely to report practicing risky sex. Loneliness and satisfaction with social support were unrelated to sexual behaviors.

Discussion

The results on individual and group behavior change show that San Francisco gay men have greatly reduced their levels of almost all high-risk sexual behaviors from 1985 to 1988. The differences between all anal sex and anal sex with ejaculation may be due to a misconception that anal sex is "safe" as long as one withdraws before ejaculating.†† This fits with our finding that there has been very little change in oral sex practices, which is another behavior considered "safe" by many in the San Francisco gay community.

Approximately three-fourths of the subjects reported that they were in either the stable low or change to low categories. The data further show that occasional relapse is now more prevalent than stable high-risk practices in this community. Prevention efforts need to shift from focusing on the initial adoption of safe sex, to a relapse prevention format, emphasizing the long-term maintenance of safer sex.

Overall, these changes may represent the most profound behavior changes ever observed in the literature on health behavior change.[10] Studies on smoking cessation, alcohol abstinence and dieting show that it is extremely difficult to maintain healthy behaviors over time. The results on prevalence replicate findings from other San Francisco studies using volunteer populations,[11,12] thus providing a consistent picture of gay sexual behavior in San Francisco.

Although results from similar studies in other parts of the country also show a reduction in high-risk behavior in this population, the degree of stability of change observed in this study may be unique to this cohort or to San Francisco. Although this is good news, it is important to place it in context. It has been estimated that more than half of the

††Ekstrand ML, Stall RD, Coates TJ, McKusick L, Morin S: Risky sex relapse: The next challenge for AIDS prevention: The AIDS Behavioral Research Project. Paper presented at the V International Conference on AIDS, Montreal, Canada, 1989.

mainstream gay community in San Francisco has been infected by HIV; any instance of risky sex with a partner of unknown serostatus thus carries an unacceptable risk. It is important to identify characteristics of relapsers and to obtain a better understanding of the reasons for relapse in order to design effective prevention programs focusing on both the acquisition and maintenance of safe sex in this population.

The most consistent predictors of high-risk behavior included demographic and behavioral variables. Younger men were more likely to engage in unprotected anal sex and those who had friends or lovers with AIDS in 1985 were less likely to practice risky sex in 1988. These findings have been replicated both in other samples of gay and bisexual men[12–14] and among heterosexual men.††† The finding that younger gay men seem to be having more difficulty changing their behaviors could be due to a variety of factors, such as greater impulsivity, having less social support for safe sex practices, feeling uncomfortable obtaining or using condoms, perceptions of invulnerability, or having poor "safe sex negotiating skills." Results from a recent study of HIV risk-taking among young gay men[14] showed that those who practiced unprotected anal intercourse reported enjoying it more, perceiving it as less risky, and had poorer communication skills than those men who did not engage in this practice. The finding that men who practice risky sex report having less social support might be related to this issue, since it is possible that younger gay men may be less involved in the network of gay organizations than are older gay men in San Francisco. This may pose a challenge to future campaigns, since it would imply that the men who need to be targeted may be the hardest to reach.

Past sexual behavior appears to be a strong predictor of future sexual behavior. However, by targeting only those who report current unsafe behaviors we run the risk of missing many men at risk for future unsafe sex, since relapse is even more common than stable high-risk practices in this population. We may thus have to develop different targeting and intervention strategies for men who relapse than for men who have never adopted safer sexual practices.

The finding that antibody positive subjects were more likely to practice unprotected anal sex in 1985 may be due to a variety of factors. This was the year the HIV antibody test first became available and it is therefore possible that the subjects had not received the results of their antibody test when engaging in risky sexual practices. It is also possible that some of these people only engaged in unprotected anal sex with other seropositive partners. However, we have no data on partner serostatus. A recent study of the impact of antibody testing on sexual behaviors in this cohort showed that knowledge of being seropositive was associated with a lower prevalence of insertive anal intercourse in 1987.‡ No differences were found in the prevalence of receptive anal intercourse, suggesting that seropositive men perceive insertive practices as the most likely way of infecting others.‡ This distinction was not made in the present study and may explain why knowledge of serostatus failed to predict overall rates of unprotected anal intercourse. In addition, the Coates, *et al*, study followed subjects until 1987, while the present study examined behavior in 1988.

In summary, the data from this study suggest that we need to target younger gay men, and possibly men who are less involved in the social networks of the gay community. The prevailing norm needs to be that any unprotected anal sex, including occasional relapse, is risky and thus unacceptable.

APPENDIX

Selected Measures

- *HIV Status*

Although HIV status has been measured at each wave of this study, only subjects who have requested knowledge of their results have received them. In wave six (January to June 1987) we asked subjects whether they had received these results and, if so, from whom they had received them. The results showed that 33.1 percent and 31.4 percent knew that they were antibody positive and negative, respectively. An additional 17.3 percent and 18.1 percent were antibody positive and negative, but denied having received their test results. In our 1985 cross-sectional analyses, we were thus only able to use HIV status alone as a predictor of sexual behavior. In the longitudinal analyses, we combined actual HIV status with reported knowledge into three predictor variables (HIV positive, knowing results; HIV negative, knowing results; and HIV positive, not knowing results). For each of the three comparisons, the target group was compared to all other subjects.

- *HIV-Related Symptoms*

We used a clinical index that was developed in a previous study of this sample and which was found to predict HIV infection, diminished skin test reactivity, and reduction in Leu 3a T cells.[16] It includes self-report of the following symptoms: new rash, diarrhea, night sweats, weight loss, persistent fever, herpes, shingles, or bullous impetigo. In addition, it was noted whether the subjects had been diagnosed with oral hairy leukoplakia or oral candidiasis during their physical examination. A subject was considered to have HIV-related symptoms if he had any two or more of these symptoms or infections.

- *Health-Related Behaviors*

Quantity and frequency of alcohol consumption were measured during the interview by asking subjects both how often they had consumed an alcoholic drink during the past six months, and how many drinks they typically consumed on these occasions. Amount was scored on a 4-point scale ranging from "1 or 2 drinks" to "7 or more drinks," while frequency was measured on a 9-point scale, ranging from "every day" to "not at all." Information on amount and frequency of alcohol consumption was then combined into a single 7-point scale, where 1 = abstinent, 2 = occasional-light, 3 = occasional-heavy, 4 = infrequent-light, 5 = infrequent-heavy, 6 = frequent-light, and 7 = frequent-heavy consumption.

Cigarette smoking was assessed by asking subjects if they had been smoking during the past month (scored dichotomously).

- *Number of Sexual Partners*

Number of male sexual partners during the previous six months was used as a continuous measure to examine whether men who engage in unprotected anal sex are more likely to have fewer or more sex partners than men who do not engage in this practice.

- *Psychosocial Measures*

Loneliness was measured using the short form of the Revised UCLA Loneliness Scale.[17] This includes those four scale items, which, using optimal subset regression techniques, best predicted scores in the self-labeling loneliness index. (Chronbach's alpha = .75.)

Depression was assessed with the Center of Epidemiological Studies Depression Scale (CESD). The CESD[18] was developed for use in studies examining the epidemiology of depression in general populations. The scale has high reliability (.77–.92) and correlates highly with other measures of depression (.55–.74).

Social Support—The instrument contains 12 questions (four tangible support items, four emotional support items, and four informational support items). Structural support was expressed in the number of people providing each type of support. Perceived support is the tabulation of satisfaction ratings of that support. Satisfaction scores range from 3 (very satisfied) to 0 (not at all satisfied) for each type of support. The present study used an instrument partly derived from the Social Support Questionnaire by Sarason, *et al*,[19] chosen because of its high stability and internal consistency. The framework used to separate the items into distinct categories of emotional, tangible, and informational support comes from the research on the health-related functions of social support provided by Schaefer, Coyne, and Lazarus.[20]

Longitudinal Predictors of Reductions in Unprotected Anal Intercourse among Gay Men in San Francisco: The AIDS Behavioral Research Project

LEON MCKUSICK, PHD, THOMAS J. COATES, PHD, STEPHEN F. MORIN, PHD, LANCE POLLACK, MA, AND COLLEEN HOFF

Abstract: Predictors of unprotected anal intercourse were examined among 508 gay men in San Francisco. The cohort was recruited in 1983–84 at which time 49.8 percent of non-monogamous men (N = 435) and 71.2 percent of monogamous men (N = 73) reported practicing unprotected anal intercourse. Only 12 percent of non-monogamous and 27.4 percent of monogamous men reported these practices in 1988. The non-monogamous men who practiced unprotected anal intercourse in 1984 were more likely to be younger, to report that unprotected anal intercourse was their favorite sexual activity, to be low in perceived efficacy to change sexual behavior, to report that friends were more likely to engage in high-risk behaviors, to have less knowledge of health guidelines, and to be less depressed at that time. Non-monogamous individuals who in 1984 reported that unprotected anal intercourse was their favorite sexual activity were more likely to practice that behavior in 1988. Those who knew their serostatus as positive were less likely to report unprotected anal intercourse in 1988. These data infer that in order to modify AIDS-related high-risk behaviors, community risk-reduction programs be differentially aimed at young persons so as to increase personal efficacy about risk reduction, challenge peer norms, promote antibody testing, and eroticize safer sexual activities. (*Am J Public Health* 1990; 80:978–983.)

Introduction

The incidence of new human immunodeficiency virus (HIV) infection, spread through male to male sexual contact, has recently been reported to be less than 1 percent per year in San Francisco.[1] This estimated low incidence rate is presumed to be due to behavior change rather than saturation of infection in the population. High-risk sexual behaviors likely to spread the virus have declined dramatically among gay men in many American urban settings.[2] Among the men in the San Francisco Men's Health Study, 44 percent reported unprotected anal intercourse receptive in 1985; this declined to 3 percent in 1988.[a] Rates of sexually transmitted diseases provide corroborative evidence of behavior change. In 1982, 13 percent of gay and bisexual men seroconverted, and there were 4,008 cases of gonococcal proctitis (GCP). In 1986, the HIV incidence among gay and bisexual men was 1 percent and there were 390 cases of GCP.[b]

Opinions vary regarding what influenced the massive changes in behavior observed in this population.[3–9] Some have drawn a close association between changes in behavior and the public education campaigns conducted in a coordinated fashion by agencies such as the San Francisco Health Department and the San Francisco AIDS Foundation.[3,4] Others have speculated that the observable presence of disease and death from HIV was responsible for individual modifications of behavior.[2,8,9] Few data have been presented to date about predictive associations between social or psychological variables and reductions in AIDS (acquired immunodeficiency syndrome) risk behaviors.[4,8] In earlier studies, we found that the number of sexual partners the previous month was positively correlated with use of sex to relieve tension and agreement that sexual freedom was linked to gay identity. Number of sexual partners was negatively correlated with awareness of the visual image of AIDS deterioration.[10] In a follow-up analysis predicting change from November 1983 to May 1984, four variables distinguished those retaining high numbers of sexual partners from those lowering the number: awareness of the visual image of AIDS deterioration, greater age, being in a primary relationship, and greater length of time since the first homosexual experience.[11]

Based on these preliminary findings, several measures were added to the 1984 and subsequent annual assessments to predict changes in high-risk behavior: measures of health belief adapted to HIV sexual behavioral risk reduction, standard measures of psychological distress, health-related variables, and measures of perceived norms for health risk activity. When the HIV antibody test was introduced, respondents were also asked whether they had been tested. Our intention was to establish a universe of possible psychological, social, and behavioral factors which may influence sexual behavioral risk for HIV transmission,[9] and to determine which of these factors predicted change over time.

Methods

Subjects and Procedures

Subjects for the AIDS Behavioral Research Project were recruited initially in 1983 and 1984 at bath houses and bars,and by advertising for individuals who were in committed relationships or who did not use bars or baths. A total of 754 men were enrolled in the sample in 1984, representing 51 percent of those approached to participate. Subjects were mailed a self-administered questionnaire each November, and asked to complete the questionnaire and return it by mail to the investigators. As of wave 5 of data collection (November 1988), 71 percent (n = 575) of the original cohort had responded to the survey. Another 8 percent (n = 61) are known to have died (either through the report of their friends or through matching in the California Death Registry). Data reported here are for 508 (67.4 percent of the original sample) men who returned every questionnaire between 1984 and 1988. Of the 508 men, 435 (57.7 percent) were non-monoga-

mous and 73 (9.7 percent) reported that they were mutually monogamous with the same person over the entire assessment period, 1984 to 1988. Age of respondents in 1984 ranged from 19 to 63 with a mean of 35.7 (S.D. = 8.37). The majority of the sample in 1984 held professional or white collar occupations (77 percent), were Caucasian (91 percent), and had attended some college (68 percent). Mean annual income was $24,000. The study has been approved annually by the Institutional Review Board of the University of California San Francisco; a Certificate of Confidentiality was also obtained from the National Institute of Mental Health to further protect the respondents.

Measures

Sexual Behavior—Respondents were asked to report whether or not they had engaged in each of 22 sexual behaviors in the previous 30 days separately for primary and secondary partners.

Preference for Unprotected Anal Intercourse—Respondents rank ordered preferences for various sexual behaviors. A subject was scored as preferring this activity if he gave it a ranking of 1 (reported by 59.9 percent or 257 of non-monogamous and 74 percent or 54 of monogamous men). *Lifetime diagnosis of a sexually transmitted disease (STD)* was scored as no or yes (37.5 percent or 148 of non-monogamous and 29.6 percent or 21 of monogamous men in the sample).

AIDS Antibody Testing Status—Respondents were asked if they had obtained AIDS antibody testing and knew their test results. Testing status as of 1988 was used for this analysis: 31.9 percent (N = 136) of the non-monogamous men and 22.9 percent (N = 16) of the monogamous men were seropositive, while 41.3 percent (N = 176) of the non-monogamous men and 35.7 percent (N = 25) of the monogamous men were seronegative. The remainder (31 percent) were either not tested or declined to answer the question.

AIDS Prodromal Symptoms—All study respondents were presented with a checklist of 11 possible symptoms of HIV infection and asked to indicate which they had experienced in the last year. The list included the following: new rash, diarrhea, night sweats, weight loss, persistent fever, herpes, shingles, bullous impetigo, fatigue, oral hairy leukoplakia, or oral candidiasis. This was coded as a dichotomous variable: zero or one symptom indicated no symptoms and two or more indicated the presence of symptoms. In 1984, 15 percent (N = 76) of non-monogamous and 16.4 percent (N = 12) of the monogamous men reported one or more AIDS prodromal symptoms.

AIDS Loss—Participants were asked in 1984 to report how many of their friends and acquaintances either currently carried an AIDS diagnosis or had died of it; 36.3 percent (N = 155) of the non-monogamous and 35.2 percent (N = 25) of the monogamous men reported two or more such individuals.

Health belief variables included the following: *Belief in AIDS Health Guidelines* assessed the respondent's agreement to eight items on a six-point scale with AIDS risk reduction guidelines (Cronbach's alpha = .70, range = 8 to 48, median = 43); *Personal Efficacy* assessed the respondent's perceptions to 13 items on a six-point scale of being able to control risk for HIV infection and perceived self control in high risk sexual situations (Cronbach's alpha = .85, range = 21 to 78, median = 56); *Perceived Susceptibility to AIDS* assessed individual's belief to six items on a six-point scale that they were personally susceptible to contracting AIDS (Cronbach's alpha = .72, range = 6 to 36, median = 25).

Depression (measured by the Brief Symptom Inventory, expressed on a five-point scale using mean scores on six items, range = .17 to 3.67, median = .50).

Two separate scales were used to assess social support for risk reduction. *Social Support-Health Promotion* asked subjects to report how many of their friends engaged in four health-promoting behaviors (Cronbach's alpha = .68, range = 2 to 16, median = 11.0); *Social Support-High Risk Behavior* measured how many friends engaged in each of six potentially health-impairing behaviors (Cronbach's alpha = .72, range = 1 to 21, median = 10).

Statistical Analyses

We chose unprotected anal intercourse (receptive or insertive) as the primary dependent variable of interest because of its proven relationship with seroconversion.[1,12–14,c] Subjects were categorized as having practiced this behavior if they reported one or more episodes of anal intercourse without a condom in the previous month with either a primary or a secondary partner. Bivariate cross-sectional relationships were examined between predictor variables and occurrence of the dependent variables using 2 × 2 contingency tables, from which were calculated odds ratios and 95% confidence intervals using SPSS-X, Version 3.1. All independent variables were scored dichotomously; continuous scale scores were divided at the median. No differences in outcomes were produced with the scales used continuously or dichotomously. Bivariate associations whose 95% CI did not include one were then entered into multiple logistic regressions to calculate adjusted odds ratios with 95% CI; these were calculated using BMDPLR, Version 1987. A logistic regression model using all variables was also calculated. This resulted in a smaller N (308 for cross-sectional analyses; 146 for longitudinal analyses for those at high risk in 1984, 152 for those not at high risk in 1984). We report here the results from both the limited and full logistic models, since the former includes more subjects and the latter may bias variable analyses less.[15] Predictor analyses were completed separately for non-monogamous men who practiced unprotected anal intercourse in 1984 (N = 212) and for those non-monogamous men who did not practice unprotected anal intercourse in 1984 (N = 214).

Analysis of Attrition Bias—Subjects in this analysis did not differ significantly from deceased subjects or those lost to follow-up on any of the sexual behavior variables reported in this paper. Deceased subjects were older (62.1 percent > 36 years; compared to 46.5 percent of the sample and 39.5 percent of lost), more likely to have been diagnosed with a sexually transmitted disease (57.7 vs 36.3 percent of the sample and 40.3 percent of lost), more likely to believe that they had been exposed to HIV (77.2 vs 58.5 percent of the sample and 59.3 percent of lost), more likely to report prodromal symptoms (31.7 vs 15 percent of the sample and 17.1 percent of lost), and more likely to perceive themselves as susceptible to AIDS (61.8 percent above the median vs 46 percent of the sample and 45.4 percent of lost).

Results

AIDS-Related Risk Behavior: 1984–1988—Figure 1 presents the percent of non-monogamous men reporting various

[c] Hessol N, Rutherford G, Lifson A, *et al:* The natural history of human immunodeficiency virus infection in a cohort of homosexual and bisexual men. Stockholm: Paper presented at the IV International Meeting on AIDS, 1988.

sexual practices in the previous month for all five assessments.

Evident in the graph is the dramatic reduction in unprotected anal intercourse (from 49.8 percent in 1984 to 12 percent in 1988), and the increases in protected anal intercourse (from 15.2 percent in 1984 to 23.8 percent in 1988) and celibacy (from 13.3 percent in 1984 to 18.6 percent in 1988). Figure 2 presents the percent of monogamous men reporting various sexual practices in the previous month for all five assessments.

Monogamous men were more likely to practice unprotected anal intercourse in 1984 (odds ratio = 2.44, 95% CI = 1.44, 4.12) and in 1988 (odds ratio = 2.75, 95% CI = 1.52, 4.97) and were less likely to practice protected anal intercourse in 1984 (odds ratio = 0.41, 95% CI = 0.16, 1.08) and in 1988 (odds ratio = 0.44, 95% CI = 0.21, 0.94). The non-monogamous men were more likely to be celibate in 1984 (odds ratio = 0.18, 95% CI = 0.04, 0.77) but not in 1988 (odds ratio = 0.77, 95% CI = 0.39, 1.53). Monogamous men, compared to non-monogamous men, were more likely to report in 1984 that unprotected anal intercourse was their favorite sexual activity (74 vs 59.9 percent, odds ratio = 1.9, 95% CI = 1.08, 3.32), to be above the median in personal efficacy (68 percent above the median vs 46 percent, odds ratio = 2.49, 95% CI = 1.43, 4.34) and less likely to believe that they were exposed to HIV (40.3 vs 61.5 percent, odds ratio = 0.42, 95% CI = 0.24, 0.72). Monogamous men were less apt to be depressed (21. 9 percent above the median vs 47.2 percent, odds ratio = 0.31, 95% CI = 0.17, 0.56), or to believe that they were susceptible to AIDS (31.4 percent above the median vs 48.5 percent, odds ratio = 0.49, 95% CI = 0.28, 0.84).

Cross-Sectional Predictors of Unprotected Anal Intercourse: 1984—Table 1 presents the bivariate relationships between each of the predictor variables and the practice of unprotected anal intercourse for the non-monogamous men. Adjusted odds ratios from the full regressions are also presented. Those who were younger, who reported that unprotected anal intercourse was their favorite sexual activity, who were lower in personal efficacy, and who were less depressed were more likely to practice unprotected anal intercourse. The limited multivariate analysis revealed the following variables to be related to the practice of unprotected anal intercourse in 1984: younger age (adjusted odds ratio = 0.54, 95% CI = 0.34, 0.87), unprotected anal intercourse as a favorite sexual activity (adjusted odds ratio = 6.92, 95% CI = 3.45, 9.18), and personal efficacy (adjusted odds ratio = 0.41, 95% CI = 0.26, 0.66). Monogamous men were more likely to practice unprotected anal intercourse in 1984 if they reported it to be their favorite sexual behavior (odds ratio = 5.97, 95% CI = 1.84, 19.34).

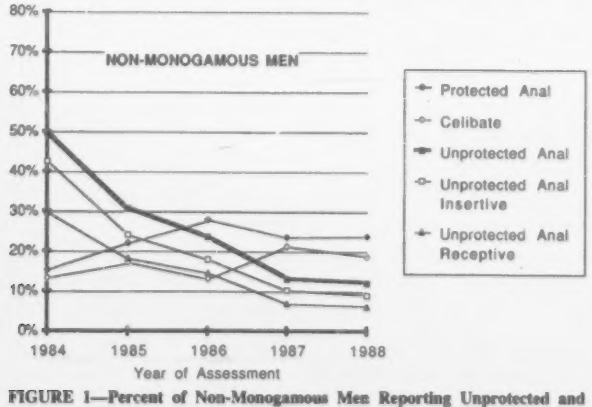

FIGURE 1—Percent of Non-Monogamous Men Reporting Unprotected and Protected Anal Intercourse and Celibacy at Each Annual Assessment

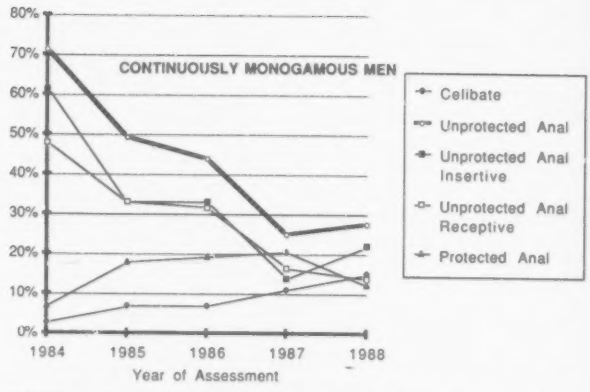

FIGURE 2—Percent of Monogamous Men Reporting Unprotected and Protected Anal Intercourse and Celibacy at Each Annual Assessment

Predictors of Change in Practice of Unprotected Anal Intercourse: 1984–88

Subjects Practicing Unprotected Anal Intercourse in 1984—There were 19.4 percent (N = 41) of the non-monogamous subjects reported practicing unprotected anal intercourse in 1988. Table 2 presents bivariate odds ratios and adjusted odds ratios from the full multivariate model to describe relationships between 1984 predictor variables and the practice of anal intercourse in 1988 for those subjects who reported unprotected anal intercourse in 1984. Unprotected anal intercourse as a favorite sexual activity predicted the practice of anal intercourse four years later. In addition, learning that one was seropositive and experiencing AIDS prodromal symptoms predicted decreased practice of unprotected anal intercourse. The adjusted odds ratios from the limited multivariate analysis were as follows: unprotected anal intercourse as a favorite sexual activity (8.26, 95% CI = 1.88, 36.23) and diagnosed as seropositive (0.37, 95% CI = 0.14, 0.99). Monogamous men who practiced unprotected anal intercourse in 1984 but did not practice it in 1988 were more likely to have been diagnosed as HIV antibody positive (odds ratio = 0.54, 95% CI = .40, .74), while those who tested antibody negative were more likely to continue the practice (odds ratio = 4.44, 95% CI = 1.25, 15.82).

Subjects Not Practicing Unprotected Anal Intercourse in 1984—Among non-monogamous subjects not practicing unprotected anal intercourse in 1984, 5.3 percent (N = 11) reported practicing this behavior in 1988. The only 1984 variable to predict this behavior in 1988 was unprotected anal intercourse as a favorite sexual behavior (odds ratio = 4.21, 95% CI = 1.08, 16.37).

Discussion

Public health campaigns designed to reduce HIV transmission through sexual relations may benefit from the examination of results such as these. Men who initially practiced unprotected anal intercourse outside of a mutually monogamous relationship, even in 1984 when risk information was disseminated widely, preferred unprotected anal intercourse,

TABLE 1—Cross-sectional Predictors of Unprotected Anal Intercourse in 1984 among Non-monogamous Men

Predictor Variables (1984)	Percent (N) Reporting Unprotected Anal Intercourse above Predictor Variable Cutoff	Bivariate Odds Ratio (95% CI)	Adjusted Odds Ratio[b] (95% CI)
Age (>36 years)	37.6 (79)[a]	0.53 (0.36, 0.78)	0.51 (0.29, 0.86)

had less personal efficacy, were younger, reported that their friends were more likely to engage in high-risk behavior, and had less belief in the importance of the health guidelines. The continued practice of unprotected anal intercourse over time was associated with preference for unprotected anal intercourse and a diagnosis of being seronegative, while a seropositive diagnosis was associated with a reduction in this behavior. Risk reduction programs may need to eroticize alternative sexual practices,[d] promote skills that increase self-efficacy,[16] modify social norms supporting high-risk behavior,[17] and encourage antibody testing so that seropositive individuals are further reinforced to reduce sexual behaviors likely to infect others with HIV.[18–22]

Unprotected anal intercourse as a favorite sexual activity strongly predicted this high-risk behavior both cross-sectionally and longitudinally. Clearly, pre-existent habit patterns and preferences promote continuation of other behaviors that are detrimental to health. Models developed for smoking cessation and alcohol addiction may be adapted to intervene in this new health threat.

Additionally, those who practiced high-risk behavior are supported by the norms they perceive in their social world. Men who initially perceived their friends and social contacts to engage in high-risk behavior were more likely to practice high-risk sex. Norms can influence behavior in two ways. First, individuals may hold norms supporting safer sex, but not share them with peers. In this instance, interpersonal mechanisms are needed for making implicit norms explicit. Secondly, some explicit norms may not support safer sex. In those cases, strategies may be needed that replace these norms with explicit norms for safer sex.[17]

The belief that one is personally capable of implementing

[d] D'Eramo JE, Quadland MD, Shatts, W, Schuman R, and Jacobs R: The 800 men project: A systematic evaluation of AIDS prevention programs demonstrating the efficacy of erotic, sexually explicit safer sex education on gay and bisexual men at risk for AIDS. Stockholm, Sweden: Paper presented at the IV International Conference on AIDS, June 1988.

safe sex practices may be necessary for behavior change. Self-efficacy was associated with lower risk cross-sectionally in 1984. Our self-efficacy items tapped the individual's skill in engaging in safer sexual practices as well as the ability to negotiate safer sex with potential sexual partners. Methods for increasing self-efficacy, especially through skill training, may reinforce HIV sexual behavioral risk reduction.

Knowledge of positive HIV antibody status was associated with reduction of sexual risk. Offering antibody testing and encouraging individuals to act on their knowledge of test results may be regarded as helpful components of an overall community behavioral health program. Receipt of test results took place in the social and legal context of HIV testing in San Francisco. Testing was available under conditions of anonymity (88 percent of the group received test results at Alternative Test Sites which used anonymous procedures) or, at the very least, confidentiality. Legal guarantees of non-discrimination based either on sexual preference or HIV antibody status have been provided in San Francisco and in California. Testing and counseling takes place in a community context of mass public education about AIDS risk reduction. Antibody testing may result in beneficial behavior change, but perhaps only when such additional resources and assurances are provided.[20,*] Knowledge of seronegative status was associated in the bivariate analyses with increased practices of unprotected anal intercourse. It was not possible, however, to determine the meaning of this finding. It might have been the case that seronegative individuals, upon learning their serostatus, sought out other seronegative men to practice their favorite behavior, or were tested upon beginning a relationship. At any rate, the potential for "silent infection" in some seronegative men should suggest that these men exercise great caution in practicing highly risky activities to avoid seroconversion.[23]

Being in a monogamous gay relationship was associated with higher risk sex throughout the entire study. The interaction of sexuality and relationship is a complex one. Other authors have reported a decrease in overall sex activity within longer term primary relationships, both heterosexual and homosexual.[24,25] However, for these respondents, the establishment of trust in a primary bond and mutual support for specific sexual habits and tastes may have led to increased sexual risk activity.

This sample may have limited generalizability in that it includes predominantly White gay males who are educated and living in San Francisco. Clearly, similar research with other groups in other cities is needed to determine if these or other factors are related longitudinally with behavior change. A recent review of behavioral factors in HIV infection[9] found the field confounded by different conceptualizations and operationalizations of concepts. Needed are standardized instruments to be applied to different communities so that the generalizability of elements of behavior change across groups and communities can be determined.[26] Missing from this analysis were data regarding alcohol and drug usage, and their relationship to high-risk sex. These variables have been found to be strongly associated in previous work.[27–29] Regrettably, because they were not included in our baseline questionnaire, they do not appear in this multivariate model. Future studies of high-risk behavior would profit from analysis of the additional contribution of drug and alcohol use in the context of the psychological and social variables already described here. Since these are self-report data, issues of social desirability with regard to reports of sexual behavior need to be considered. When these respondents were recruited they were given thorough reassurances of confidentially, and they have been followed with repeat assessments for many years, giving us less reason to suspect dishonest reporting. Analyses comparing those who dropped out with continuers found few significant differences in reported frequencies of target sex behaviors. Although the magnitude of change in sexual behavior cannot be determined precisely by self-report methods, the trends described by this research closely parallel changes described in other behavioral studies in San Francisco described above.

The Mortality Profile of Black Seventh-Day Adventists Residing in Metropolitan Atlanta: A Pilot Study

FREDERICK G. MURPHY, MSPH, MPIA, DANIEL S. BLUMENTHAL, MD, MPH, JOANN DICKSON-SMITH, MSPH, AND RALPH P. PEAY, MPH

Abstract: Mortality information was gathered for 110 Black Seventh-day Adventist members of seven churches in Metropolitan Atlanta, Georgia during the period 1980–87. Seventy-seven percent of the deaths were due to cardiovascular diseases; 8 percent due to cancer, the second leading cause of death. The cancer rate is extremely low in comparison to the proportion of deaths due to cardiovascular diseases. Subsequent research on this population will take into consideration lifestyle factors which could contribute to this finding. (*Am J Public Health* 1990; 80:984–985.)

Introduction

Differences in mortality rates and life expectancy between Black and White Americans are well known,[1–4] as are reduced disease specific mortality rates among certain religious groups whose lifestyles protect them from various risk factors.[5,6] Black Seventh-day Adventists are a group whose race is at high risk for early death but whose lifestyle may reduce that risk substantially. Black Seventh-day Adventists residing in the Metropolitan Atlanta, Georgia area who are members of the South Atlantic Conference of Seventh-day Adventists have not been previously studied.

Seventh-day Adventist doctrine warns its members, for reasons of health and temperance, not to consume caffeine, tobacco, alcohol, illegal drugs, or pork products.[7–9] Although vegetarianism is not required, it is highly recommended. The doctrine also warns against seeking entertainment in establishments where consumption of proscribed substances take place. It further indicates that health risks can result from such attendance.[6,10] This brief investigation examines mortality among Black Seventh-day Adventists living in Metropolitan Atlanta, Georgia during the seven-year period 1980–87.

From the Morehouse School of Medicine, Department of Community Health and Preventive Medicine, and the South Atlantic Conference of Seventh-Day Adventist in Atlanta, GA. Address reprint requests to Frederick G. Murphy, MSPH, Division of Diabetes Translation, Center for Chronic Disease Prevention and Health Promotion, Centers for Disease Control, 1600 Clifton Road, Mailstop E-08 Atlanta, GA 30333. Mr. Murphy was lead public health investigator for this pilot study and community organizer at Morehouse School of Medicine; Dr. Blumenthal, research consultant for the study, is chairman of the Department of Community Health and Preventive Medicine at Morehouse; Ms. Dickson-Smith, primary researcher for the study, is currently an intervention specialist at CDC; Mr. Peay, research consultant for the study, is currently President of the South Atlantic Conference of Seventh-Day Adventist. This paper, submitted to the Journal July 14, 1989, was revised and accepted for publication January 25, 1990.

Methods

The seven Black Seventh-day Adventist churches included in this study are established members of the South Atlantic Conference of Seventh-day Adventists also based in Atlanta, Georgia. Black Seventh-day Adventist membership in Atlanta grew from 3,366 in 1980 to 6,002 in 1987. Three of the seven churches were established after 1984.

All deaths among members of Adventist churches are reported to regional conferences on a quarterly basis by church clerks. This is part of a conference policy which requires each of its churches to report the names of all individuals dropped from church rolls due to death, apostasy, or lack of attendance. The death portion of these reports contain only the name of the deceased individual, the year of death, and the church with which he/she was affiliated.

We manually retrieved all quarterly reports submitted to the South Atlantic Conference Office between the years 1980 and 1987. Death information and data from each of these were then matched to death certificates at the Georgia Department of Vital Records. Data on the decedents' age at death, sex, and race were obtained from each available death certificate.

Results

Reports of 116 deaths were obtained from the South Atlantic Conference of Seventh-day Adventist. The year of death was not listed for six and could not be matched to death certificates in the State of Georgia Department of Vital Records. We were able to match the remaining 110.

Table 1 shows the distribution and average age at death by sex for the 110 matched death certificates. The female predominance is consistent with the approximately 2:1 (female:male) ratio in Black Seventh-day Adventist church membership in Atlanta.

Table 2 shows the number of deaths attributed to each

TABLE 1—Distribution of Deaths and Average Age at Death by Sex, Metropolitan Atlanta Seventh Day Adventists

Sex	Number of Deaths	Age at Death (years)		
		Average	Median	Range
Male	42	66.4	59	50–96
Female	68	77.4	71	55–104
Total	110	71.5	70	50–104

Metro-Atlanta Minority SDA Mortality Profile

TABLE 2—Total Deaths by Specific Cause and Sex

Cause of Death	Male	Female	ICD Codes A	ICD Codes B	Total

ICD Code B = Second most frequently used code

specific cause of mortality. Cardiovascular disease accounted for 82.3 percent of the deaths in women and 69 percent in men. All four of the homicide deaths were among males.

Discussion

Although based on relatively small numbers of deaths, the results are suggestive. For example, cancer deaths were relatively rare in this pilot study. This could be attributed, at least in part, to abstinence from use of tobacco and alcohol, and a relatively low-fat diet (due to a high prevalence of vegetarianism) among Seventh-day Adventists.[6,8,9,11] This high proportion of cardiovascular disease deaths among this group could be the result of the large number of elderly persons in the group.

Additional research focused on Black Seventh-day Adventists will be required in larger numbers so that more detailed information can be gathered. Phase II of this investigation is currently being proposed.

ACKNOWLEDGMENTS

The authors would like to acknowledge the staff of the South Atlantic Conference of Seventh-day Adventists and the Berean Seventh-day Adventists Church for their assistance and cooperation in the preliminary initiative. A special thanks to V. J. Mendinghall, Secretary of the South Atlantic Conference of Seventh-day Adventists for his patience and dedication to this pilot study; also, to Dr. Gene McGrady, at the Morehouse School of Medicine, for his review and comment on this manuscript.

Disaster Medical Assistant Team Formed in Atlanta

An Adult Disaster Medical Assistance Team has been formed in Atlanta, Georgia, as part of the National Disaster Medical System, a joint effort of a number of federal agencies. The system will provide help in the event of a disaster large enough to overwhelm state and local resources.

This team of health volunteer personnel from the greater Atlanta area will function under the supervision of Clayton General Hospital—the hospital designated to help coordinate medical assistance units that travel to disaster sites. This is the second team formed in Atlanta this year. In March, the Henrietta Egleston Hospital for Children formed a Pediatric Disaster Medical Assistance Team.

More information is available from the Office of Emergency Preparedness, HRSA, 5600 Fishers Lane, Rm 14-48, Rockville, MD 20857. Tel: (301) 443-6580.

Playground Hazards in Atlanta Child Care Centers

JEFFREY J. SACKS, MD, MPH, KENNETH W. HOLT, MSEH, PATRICIA HOLMGREEN, MS, LEWIS S. COLWELL, JR., AND J. MARION BROWN, JR., BS

Abstract: We identified 684 playground hazards in 66 child care centers despite regulations mandating that the grounds be hazard-free. Of 21 centers with ≤5 hazards, 42.9 percent reported a playground-related injury in the previous year; of 25 centers with 6–11 hazards, 52.0 percent reported a playground-related injury; and of 20 centers with ≥12 hazards, 60.0 percent reported a playground-related injury. Climbing equipment ≥6 feet tall generally had inadequate impact-absorbing undersurfacing and had over twice the rate of fall injuries as climbing equipment <6 feet. (*Am J Public Health* 1990; 80:986–988.)

Introduction

Investigators of medically attended injuries among children attending child care centers found that 47 percent of injuries occurred on the playground.[1] During a 2,000-hour year (40 hours per week × 50 weeks), an estimated 1.64 percent of children in a center will incur a playground-related injury requiring medical evaluation; 0.98 percent will incur a playground equipment-associated injury, and 0.42 percent will incur a climber-related injury.[1] In an attempt to understand why so many injuries occur on playgrounds, we evaluated playground hazards at 66 child care centers.

Methods

The methods of the injury study have been described in detail elsewhere.[1] Briefly, 80 of the 605 licensed centers in Atlanta were randomly selected, and 71 participated in a study of medically attended injuries from June 1987 through May 1988. Of those 71 centers, one had no playground; by the time this study began, one center had replaced its playground, and three centers had closed. Directors of the remaining 66 centers allowed us to evaluate their playgrounds.

Between July and October 1988, two of three evaluators (KWH, LSC, and JMB) visited each participating center. Safety hazards evaluated are listed in Table 1 and included those defined by the Statewide Comprehensive Injury Prevention Program of the Massachusetts Department of Public Health and others.[2–5] Any hazards from playground changes made after March 1, 1988 were excluded from analysis. After the inspection, the director was shown the safety problems identified and given information about playground safety.

Equipment height was measured from the ground to the maximum height that a child's feet can reach. The undersurface (grass, sand, wood chips, etc.) below each piece of equipment was recorded. The undersurface's minimum depth was measured below the point of maximum attainable height.

TABLE 1—Playground Equipment-associated Hazards Identified, Atlanta Child Care Centers, 1988

Type of Equipment-associated Hazard	Number of Times Identified: All Equipment	Number of Times Identified: Climbers Only
Rock, concrete, root or stump in fall zone	171	35
Inadequate clearance*	56	30
Sharp protrusion	42	17
Contaminants in undersurface	38	9
Missing part	31	11
Blunt protrusion	29	14
Trip-and-fall hazard	27	4
Loose parts	21	7
Open "S hook	20	0
Tip-over hazard	18	8
Entrapment hazard	16	12
Hard swing seats	13	0
Broken parts	12	0
Other**	34	10
All equipment-associated hazards	528	157

*Inadequate clearance was defined as an obstruction (fence, wall, etc.) within 4 feet of a climber or within 8 feet of the arc of a swing.
**Other includes all equipment-associated hazards appearing <12 times in surveyed playgrounds.

Results

The 66 centers had 135 playgrounds. At 21 (15.6%) playgrounds we identified no hazards; at 114 playgrounds we identified a median of five hazards (range 1–16). Only one center had no playground hazards identified; the other centers had a median of eight playground hazards (range 1–28).

Hazards Unrelated to Equipment

At 66 (48.9 percent) playgrounds we identified a total of 156 hazards unrelated to equipment (median = 2; range = 1–8). Twenty-eight (20.7 percent) playgrounds had gaps in the fencing wide enough for a child to go through. At 11 playgrounds, children could enter a hazardous area within the playground (e.g., a storage shed). Poison ivy was found on four playgrounds, briars on five, and broken glass on five. Other hazards noted included 33 trip-and-fall hazards, 27 protruding rocks, tree stumps, or concrete pieces; and 23 sharp protrusions.

Equipment-associated Hazards

One hundred and eleven (82.2 percent) playgrounds had an equipment-associated hazard (median = 4; range = 1–13). Although climbers, swings, and slides accounted for 52.2 percent of the equipment (Table 2), they were associated with 65.3 percent of the hazards. Hazards were associated with 36.1 percent of the equipment; by type, swings were the most frequently associated with a hazard, followed by spring riders

**Not including inadequacy of undersurface.
***Number of swing seats = 518.

and climbers. The most frequently encountered equipment-associated hazards were hard objects in fall zones (Table 1).

Undersurface below Climbers

The most common surface below climbing equipment was earth or grass (60.6 percent) (Table 3). Impact-absorbing loose-fill materials (e.g., sand or wood chips) were beneath 38.2 percent of climbers, but only 4.2 percent had depths of ≥4 inches. About 27 percent of the climbers were ≥6 feet high and only two (2.9 percent) of those had rubber matting or ≥4 inches of loose-fill material beneath.

Relationship of Hazards to Injuries

During the one-year injury study,[1] of 21 centers with ≤5 hazards, 42.9 percent had reported a playground-related injury; of 25 centers with 6–11 hazards, 52.0 percent reported a playground-related injury; and of 20 centers with ≥12 hazards, 60.0 percent reported a playground-related injury. This same trend was noted for equipment-associated and climber-related hazards and reporting of equipment- and climber-related injuries.

We could not identify two involved climbers for 15 climber-related fall injuries reported in the injury study.[1] Of the 13 pieces of climbing equipment associated with a fall injury, 46.2 percent were ≥6 feet compared to 26.4 percent of climbers unassociated with a fall injury. Climbers ≥6 feet tall had 8.8 medically attended fall injuries per 100 pieces of equipment compared to 3.9 per 100 for climbers <6 feet tall (Table 3).

Six other injuries appeared associated with identified hazards. One head injury occurred from a fall from a broken swing seat. A dental injury resulted from a fall off a bridge with no handrail. One fracture occurred from a fall off a 6.3 foot high slide with an earth undersurface and exposed concrete anchoring. One fracture occurred from a fall off a balance beam 3.3 feet above ½ inch of pea gravel. One fracture and one bruise caused by tripping occurred on playgrounds with tripping hazards.

TABLE 3—Surface and Surface Depth Beneath Climbing Equipment, by Height of Climber and Number and Rate of Medically Attended Fall Injuries, Atlanta Child Care Centers, 1988

Discussion

At child care centers, most injuries that require medical attention occur on playgrounds.[1,6,7] Of the playgrounds we studied, 84 percent contained a hazard. As the number of hazards increased, so did the likelihood a playground-related injury was reported.

Climbers have been associated with a disproportionate number of playground injuries.[1,6,8–10] Although climbers constituted 23.6 percent of study center equipment, they were involved in 42.5 percent of the equipment-associated injuries.[1] Moreover, the rate of fall injuries increased with the height of the climbing equipment.

In our study, 27 percent of climbers were ≥6 feet high and 61 percent had earth or grass underneath. Earth and grass are not considered suitable undersurfaces for climbers ≥4 feet high.[11–12] If loose-fill material is the undersurface, depths of ≥6 inches are recommended[2,11]; yet, the centers we studied rarely had loose-fill materials at recommended depths. Those responsible for school playgrounds have been found legally negligent for failing to provide adequate undersurfacing beneath equipment.[13]

Despite Georgia State regulations for child care centers mandating that climbing equipment be securely stationed, 5 percent of climbers had tip-over hazards. These regulations require that the playground be fenced; yet, 21 percent of the playgrounds studied had fencing gaps large enough to permit a child to pass through. Although prohibited on center grounds, "hazardous conditions" are not defined in the regulations. Although Georgia codes mandate "resilient surfaces" beneath climbers, they do not specify the types and depths of surfaces that satisfy this definition.

We believe that regulations regarding child care center playgrounds should be more specific and better enforced. In addition, regulators, center directors, and parents should be educated about playground hazards and prevention of playground injuries.[3,14,15]

A Personal Monitoring Study to Assess Workplace Exposure to Environmental Tobacco Smoke

DAVID B. COULTAS, MD, JONATHAN M. SAMET, MD, JOHN F. MCCARTHY, ScD, AND JOHN D. SPENGLER, PhD

Abstract: We enrolled 15 nonsmoking volunteers to evaluate the feasibility of measuring personal exposure to environmental tobacco smoke (ETS) at work and to characterize workplace exposures. During one workshift, we obtained questionnaires on exposure, saliva and urine for cotinine, and personal air samples for respirable particles and nicotine. The levels of cotinine, respirable particles, and nicotine varied widely with self-reports of exposure to ETS, but on average increased with increasing exposure. (*Am J Public Health* 1990; 80:988–990.)

Introduction

While health effects of passive smoking on children and adults have been identified, the principal location of exposure investigated has been the home.[1,2] Workplace exposure has received less attention, and health effects of environmental tobacco smoke (ETS) in the workplace remain controversial.

We enrolled 15 nonsmoking adults to determine the feasibility of measuring personal exposure to ETS at work and to characterize workplace exposures of this small group of subjects. Indicators of exposure, measured during a workday, included questionnaires, personal samples for respirable particles (RSP) and nicotine, and urinary and salivary cotinine.

Methods

Between October 1986 and May 1987, 15 nonsmoking volunteers (eight men, seven women), 18 years of age and older, were recruited from the Albuquerque, New Mexico area. We obtained exposure questionnaires, saliva, urine, and personal air particle samples during one workshift. The saliva and urine specimens were obtained before and after the workshift. Cotinine was quantitated by a double antibody radioimmunoassay, as described by Langone, *et al.*[3] Details of the assay in our laboratory have been reported previously.[4]

During the workshift, each subject wore a personal monitoring pump running at 1.7 l/min with a 10 mm nylon cyclone clipped to the shirt collar.[5] RSP samples were collected on 37 mm Fluropore filters (Millipore Corp). Nicotine was collected on a glass fiber backup filter treated with sodium bisulfate to minimize volatilization; after extraction from the filter, analysis for nicotine was done on a gas chromatograph with a flame ionization detector.[6] The recovery of nicotine by this procedure has been shown to be 98 percent efficient.

From the questionnaires, we derived measures of exposure including the total number of cigarette smokers and total number of hours exposed during the workshift. To describe the relationships among the measures of ETS exposure, Spearman correlations were calculated. Data analysis was performed with standard programs.[7]

Results

Occupations of the subjects were diverse (Table 1); mean age was 44.8 years; average duration of the workshift and of the personal monitoring was 6.5 hours (SD ± 2.0).

Exposure to cigarette smokers at work was reported by 13 of the 15 participants. Of the 13 reporting exposure, two reported exposure to crowds of smokers during their workshift and the remaining 11 encountered a mean of 8.8 smokers (SD ± 6.7). The mean reported hours of exposure was 3.4 (SD ± 2.1).

Respirable particle and nicotine concentrations varied widely with the reported number of smokers and hours of exposure. The mean concentrations for RSP and nicotine were 63.9 $\mu g/m^3$ (SD ± 41.5) and 20.4 $\mu g/m^3$ (SD ± 20.6), respectively. Correlations between the atmospheric markers

Volunteer/Hospital	4/3	27.6	6.3
Volunteer/Hospital	4/3	25.2	8.7
Volunteer/Hospital	4/4	53.2	53.2

and the questionnaire measures of exposure to ETS were moderate (Table 2).

As was observed for the atmospheric markers, the post-workshift urinary and salivary cotinine levels varied widely with self-reported exposure. In comparison with pre-workshift levels, post-workshift levels were not consistently increased. The mean pre-workshift urinary and salivary cotinine concentrations were 31.8 ng/mg Cr (SD ± 67.6) and 2.9 ng/ml (SD ± 5.0), respectively. For the post-workshift levels, the corresponding values were 19.7 ng/mg Cr (SD ± 43.2) and 3.5 ng/ml (SD ± 5.9).

Spearman correlation coefficients were calculated to examine the relations among the questionnaire variables, the atmospheric markers, and urinary and salivary cotinine (Table 2). Moderate correlations were obtained for self-reports and cotinine levels, and nicotine levels and cotinine levels. However, RSP levels and cotinine concentrations were not correlated.

TABLE 2—Spearman Correlations between Various Measures of Environmental Tobacco Smoke at Work, New Mexico, 1986–87

Correlated Measures	N	r

Discussion

The controversial effects of involuntary smoking in the workplace need further investigation. The conduct of such research would be facilitated by the development of unintrusive and accurate methods of exposure assessment. Alternative approaches include active and passive monitoring, biological markers, and questionnaires. We have shown that personal monitoring for tobacco smoke components can be accomplished in the workplace. However, many employers and employees would not participate in the study because of concern about the wearing of pumps.

Despite the small number of subjects studied in this investigation, objective evidence of exposure to ETS was obtained in various workplaces. The levels of RSP and nicotine were similar to those observed in other investigations.[6,8–10] However, few of these studies included information on the intensity and duration of exposure to ETS.[10]

We observed moderate positive correlations among the questionnaire measures of ETS exposure, the results of personal monitoring for RSP and nicotine, and measurements of urinary cotinine. Each of these types of measures provides a differing index of exposure to ETS.[1] The questionnaire measures that were used assess source strength, but concentrations of ETS are also influenced by room volume and ventilation. Nicotine is a specific marker of exposure to ETS, whereas RSP is nonspecific. Cotinine levels reflect nicotine exposure, but also are determined by timing of specimen collection[10] and uptake and metabolism. Thus, tight concordance among these broad indicators of exposure used in this study would not be anticipated.

Because of the differing characteristics of questionnaires, personal monitoring, and biological markers for assessing ETS exposure, no single method should be considered as optimal for studying the workplace. We recommend that assessment of ETS exposure in indoor environments should utilize multiple approaches to characterize short- and long-term exposures. In population studies, questionnaire measures of exposure offer the simplest approach with personal atmospheric markers and biologic markers providing methods for estimating the potential magnitude of misclassification of self-reported exposure.

ACKNOWLEDGMENTS

The authors thank Dr. Helen Van Vunakis for providing the reagents for the radioimmunoassay and Irene Walkiw for technical assistance in performing the assays.

Sexual Histories of Heterosexual Couples with One HIV-Infected Partner

NANCY S. PADIAN, MPH, PHD

Abstract: Ninety-eight heterosexual couples enrolled in a HIV transmission study, at least one of whom was HIV-infected, were interviewed about sexual behavior. Although males and females were interviewed separately, there was agreement between them on the number of sexual contacts, the practice or anal intercourse, and condom use. These findings of strong reliability are encouraging, but do not necessarily imply that the data are valid. (*Am J Public Health* 1990; 80:990–991.)

Introduction

The best way to prevent the spread of infection from human immunodeficiency virus (HIV) is voluntary behavioral change.[1] Before recommending strategies to promote such changes, one must first establish the kinds of behavior currently practiced. To do so, AIDS (acquired immunodeficiency syndrome) researchers rely almost exclusively on interviewing techniques, but many question the validity and reliability of this methodology.[2] For example, in a study of the reproductive histories of a group of women, Hornsby and Wilcox[3] established that daily logs of sexual behavior were more accurate than comparable data collected through retrospective interviews. Similar results were found by both Udry and Morris[4] and Kunin and Ames,[5] who determined that recent and frequent reporting of sexual behavior produced the most precise results. However, AIDS epidemiologists may not have the opportunity to collect data on a regular basis and are thus forced to rely on retrospective reports of behavior even though the accuracy of these reports (especially for a variety of sexual practices) has not been established. Here I report on the reliability of such data, comparing reports of sexual behavior between men and women in couples of which at least one partner was HIV seropositive.

Methods

Since 1985 we have been conducting a study of the heterosexual transmission of acquired immunodeficiency syndrome (AIDS) in California in which we enroll the opposite sex partners of individuals infected with HIV. Although the study began by enrolling the female partners of HIV-infected men,[6] in 1987 we began to enroll participants as couples. Individuals who test positive for HIV at a variety of sites and who also have heterosexual partners are referred to the study as part of their post-test counseling. Enrollment is voluntary; study protocol is described elsewhere.[6]

Interviewers are female and are matched to couples by ethnicity. They are trained in group and individual sessions that include role playing and interpretation of interview responses. Results were reliable across interviewers. To ascertain number of sexual contacts, the interviewer asks how many times the couple has sexual intercourse in a typical week or month. Deviations from this number throughout the relationship are noted. The total number of contacts is estimated by multiplying the duration of the relationship by the typical reported amount and weighting this number by changes in sexual activity over time. Individuals in the couple are interviewed separately on the same day.

Behaviors considered in this report are: vaginal intercourse, anal intercourse, and condom use. Continuous responses were compared using Pearson's correlation coefficient, and categorical responses were compared using the Kappa coefficient and its corresponding confidence limits as described by Fleiss.[7] HIV infection was ascertained from serological tests using enzyme immunoassays with Western Blot confirmation.

Results

This report includes data from 98 couples, 68 percent of which were monogamous at entry into the study. Most of the men and women reported only one partner in the six months prior to entry into the study. Median number of partners since 1978 (the beginning of the AIDS epidemic) was five for the women and 10 for the men. The overall male-to-female transmission rate from the study which began in 1985 was 24 percent. Seventy-seven of the couples included infected men and their female partners; 12 (16 percent) of these women were infected. Twenty-one of the couples were infected women and their male partners; none of these men were infected. The reported risk group of the infected partner of the 98 couples varied and is described in Table 1. Sixty-three percent of the couples were White, 20 percent Latino, 7 percent Black, 1 percent Asian, and the remainder were couples of mixed ethnicity. Average income for the couples was $20–29,000 per year; average level of education was 13

No Identified Risk	9 (12)	3 (14)

school years. The couples had been together from one month (four contacts) to 19 years (greater than 3,000 contacts).

The total number of vaginal intercourse contacts reported by the man and the woman were highly correlated (r = .84, 95% CI = .64, 1). Because the couples knew they were to be interviewed about their sexual behavior, they may have discussed responses to anticipated questions. In fact, some of their responses were identical, but there was still agreement between those partners with non-identical responses (r = .72, 95% CI = .44, 1). Women reported more vaginal contacts than their male partners for the duration of the relationship, but this was not a significant difference (mean estimated number of contacts was 540 by women versus 508 by men). Agreement was stronger for the couples with briefer relationships.

Number of anal intercourse contacts was compared as a continuous variable, with somewhat less strong agreement (r = .44, 95% CI = .13, .74). Responses on anal intercourse as a dichotomous variable (ever versus never) compared using the Kappa coefficient, agreed well (Kappa = .76, 95% CI = .56, .95) (Table 2). Responses on condom use treated as a dichotomous variable (Table 3) also agreed well (Kappa = .74, 95% CI = .54, .94). Two couples who disagreed about the practice of anal intercourse also disagreed about the practice of condom use. The small number of couples and high levels of agreement precluded analyzing differences by risk group of the index case, ethnicity, gender, number of sexual partners, or duration of the relationship.

Discussion

In this group of heterosexual couples with one HIV-infected partner, agreement about sexual practices was observed. Couples agreed somewhat better on the number of contacts of vaginal than anal intercourse. These patterns are similar to those observed by Seage, *et al*[8] in homosexual couples.

Participation was voluntary and the results might not apply to all heterosexual couples with one infected partner. In addition, this evidence of good reliability does not necessarily imply validity. For example, measurements were not independent because couples may have discussed responses prior to the interview.

The occasional disagreement among partners suggests that researchers still must be cautious in relying on the reports of sexual behaviors they are examining. We intend to examine this phenomenon further by assessing willingness to discuss HIV risk and serostatus between partners. Kegeles, *et al*[9] found that HIV-infected homosexual men were not completely forthright in discussing their antibody status with non-primary partners. These results remain to be examined between heterosexual partners.

Maintenance of Nonsmoking Postpartum by Women Who Stopped Smoking during Pregnancy

PATRICIA DOLAN MULLEN, DRPH, VIRGINIA P. QUINN, MPH, AND DANIEL H. ERSHOFF, DRPH

Abstract: This paper describes self-reported maintenance of nonsmoking at six months postpartum by women whose abstinence was verified beginning before the 20th week of pregnancy and continuing through delivery (n = 134). The overall maintenance rate of 37 percent was not related to sociodemographic characteristics, smoking and obstetric history, the time when quitting occurred, or a prenatal smoking cessation program. Although this rate is encouraging, more attention should be directed to sustaining prenatal abstinence from smoking beyond delivery. (*Am J Public Health* 1990; 80:992–994.)

Introduction

Many women smokers refrain from smoking while they are pregnant. Randomized trials of prenatal smoking cessation programs have found net differences of 12–25 percentage points,[1–3] with corresponding positive effects on pregnancy outcomes[1,4–6] and health care costs.[6] Even more women who smoked prior to pregnancy (16–41 percent)[1–3,7,8] stop smoking in response to pregnancy before they begin prenatal care, and 65–80 percent of those "spontaneous quitters" maintain abstinence throughout pregnancy.[1,9] Rates of relapse postpartum, however, may be high.[10–13] This is of concern because of growing evidence that parental smoking compromises infant health[14] in addition to that of the mother. This study addresses the following questions:

- How much prenatal smoking cessation is sustained after delivery?
- Do prenatal intervention programs negatively affect postpartum maintenance, as suggested in previous findings?[14]
- What are the characteristics of women who maintain abstinence?
- How soon do women return to smoking?

Methods

All English-speaking pregnant women entering care by the 18th week of pregnancy between July 1985 and June 1987 in one of five health centers of a large multispecialty medical group practice in Los Angeles affiliated with Maxicare Health Plans, Inc, comprised the study population. Those who reported smoking ≥7 cigarettes per week before becoming pregnant (23 percent) were randomly assigned to the experimental program or usual care. Of these (n = 541), 59 percent were intake smokers; 41 percent were spontaneous quitters. Characteristics of the multi-ethnic study subjects are described elsewhere.[3,9] The study tested the effectiveness of a serialized self-help smoking cessation program, the first part of which was given at the intake visit; and the remainder were mailed weekly thereafter.[3]

This analysis is of women who continued their pregnancies as medical group and health plan enrollees and who achieved optimal prenatal smoking cessation (see Table 1). For intake smokers, optimal cessation was defined as quitting before the 20th week of pregnancy. Maintenance for intake smokers and spontaneous quitters was assessed biochemically over the course of pregnancy (average tests per subject = three). Rates of optimal quitting were as follows: Intake smokers, 22.2 percent in the experimental group versus 8.6 percent among the controls; spontaneous quitters, 83.7 versus 78.6 percent.

Data for the present analysis were from a questionnaire and interview at the intake visit and a telephone interview six months after delivery that embedded questions about smoking and other health-related behaviors in questions assessing satisfaction with health services.[3] Postpartum maintenance was defined as self-reported nonsmoking throughout the six months since the birth of the baby. Subpatterns and their prevalence are summarized in Figure 1.

FIGURE 1—Patterns of Postpartum Smoking among Prenatal Quitters (& of total) (n = 134)

Telephone interviews were completed for 134 of the 140 women (96 percent) eligible for follow-up (see Table 1). Comparison of the 134 subjects for whom data were available with the 32 who disenrolled or refused revealed no significant differences in demographic, obstetric history, or smoking history variables (data available on request to author).

Results

Table 2 describes the characteristics of prenatal quitters. The overall maintenance rate was 37.1 percent. Rates did not differ significantly by intake smoking status. Among the spontaneous quitters, experimental status was not related to maintenance. The number of intake smokers was too small to analyze by experimental group status. There were no statistically significant differences ($p > 0.05$) between maintainers and relapsers in sociodemographic characteristics, smoking history, or obstetric history.

Twenty-six percent of the sample reported that they had resumed smoking by the end of the 6th postpartum week (Figure 2). This represented 43 percent of the relapse that occurred. By the end of the third postpartum month, 43 percent had relapsed (71 percent of the six-month total).

Discussion

The findings from this study indicate that some prenatal abstinence is sustained postpartum. Although this is based on self-reported smoking status in the postpartum period, two facts offer reassurance: the sample included women whose reported cessation was validated throughout pregnancy, a more sensitive time to report the behavior; and the focus on smoking was masked by questions about other health practices and the health plan services.

The follow-up period in the present study was shorter than the standard of one year in smoking cessation studies. It is likely that much of the relapse was captured, however. In the National Health Interview Study,[7] 95 percent of return to smoking that was reported at 12 months had occurred by six months; this marked leveling off has been observed elsewhere.[10,15,16] Because of the powerful motivation aroused by the pregnancy, the "post-program" period is defined as beginning with the birth. In fact, however, contact with the program in the present study ceased an average of four months earlier, so the measurement period for the intervention group could be viewed as approaching 12 months. Also, return to work and resumption of alcohol and caffeine, potential sources of stress and cues to smoke, already had occurred in most study subjects. Breastfeeding had ceased for all but one woman.

A strength of this study is the presentation of data on rates of return to smoking in a population with verified and continuous abstinence during pregnancy. Further, the definition of maintenance was relatively conservative.[16] Refusers were counted as smokers.

The rate of nonsmoking postpartum was higher in this study compared to findings from other studies. In the same

*Includes six women who refused the interview who were considered to be smokers.

population and with a similar intervention but a point prevalence measure of prenatal cessation, the six-week postpartum maintenance rate was 46 percent versus 74 percent in the present study.[12] The three-month postpartum maintenance rate found in an intervention trial in Baltimore[13] was 25 percent for treatment group members versus 57 percent in the present study. The Baltimore population smoked more heavily before pregnancy, had prenatal smoking status assessed only at the eighth month, and had a more intensive intervention including a home visit which may have boosted short-term quitting artificially.

The present results are similar to those reported for six months postpartum in the two other studies that could be located, the National Health Interview followback study[7] and a followup survey of Minneapolis/St. Paul area birth announcements.[17] Both of these groups included spontaneous quitters and used retrospective reports of smoking status during pregnancy. The definitions of prenatal cessation used in these studies did not preclude cessation of shorter duration than the present study.

Within the limitation of small numbers available for sub-analyses, rates of maintenance appeared to be unrelated to smoking status at the first prenatal visit (intake smokers versus spontaneous quitters). Sexton and coworkers[13] found a higher rate of continued abstinence among spontaneous quitters. Because there might be a rebound effect resulting from the emphasis on cessation to protect the fetus, we looked for but did not find any negative effects of the intervention.

These findings suggest that prenatal smoking cessation does carry over to the postpartum period but that exclusive concentration on the prenatal period is not enough. To capitalize further on the opportunity presented to reduce rates of smoking among young women and to protect the health of their offspring, future research should be directed toward the development and testing of intervention programs for late pregnancy and the early postpartum period.

ACKNOWLEDGMENTS

This research was supported by the National Center for Health Services Research and Health Care Technology Assessment (HS-05128) and Maxicare Health Plans, Inc. The authors wish to thank our project officer, Mrs. Jean Carmody. We gratefully acknowledge the assistance of Maxicare Health Plans, Inc, and the medical and administrative staff of Hawthorne Community Medical Group. Drs. Brian Danaher, Ellen Gritz, and Barbara Berman developed the self-help intervention program. Tracy Tobias and Pamela Smith gathered the intake data and introduced the intervention program; Wendy Kalisher conducted the postpartum interviews.

An earlier version of this paper was presented at the 117th Annual Meeting of the American Public Health Association, Chicago IL, October 22–26, 1989.

Changes in Needle Sharing Behavior among Intravenous Drug Users: San Francisco, 1986–88

JOSEPH R. GUYDISH, PHD, AL ABRAMOWITZ, MS, WILLIAM WOODS, PHD, DENNIS M. BLACK, PHD, AND JAMES L. SORENSEN, PHD

Abstract: We analyzed data for San Francisco intravenous drug users entering treatment, April 1986–September 1988 (N = 7,660). The proportion of cases reporting any needle sharing in the month preceding treatment decreased from 50 percent in 1986 to 28 percent in 1988. Similar decreases were reported by two longitudinal cohorts (needle sharing by the same individuals) admitted in 1986 and 1987 (n = 303), and in 1986 and 1988 (n = 205). In a multiple logistic regression model four variables predicted needle sharing: earlier time of admission, cocaine use, younger age, and being White rather than Black. (*Am J Public Health* 1990; 80:995–997.)

Introduction

Successful and sustained risk reduction among intravenous drug users (IVDUs) is vital in slowing the spread of the human immunodeficiency virus (HIV) in the United States. Injectable drug use is implicated in 27 percent of adult acquired immunodeficiency syndrome (AIDS) cases, and this figure is substantially higher for Blacks (45 percent) and Hispanics (47 percent). Well over half of all heterosexually transmitted cases and pediatric cases are among sexual partners and children of IVDUs.[1]

HIV prevention strategies targeting IVDUs, in addition to drug abuse treatment, now include grassroots efforts,[2] clinic-based interventions,[3,4] street outreach projects,[5] community-based information and awareness campaigns,[6] and publicly supported,[7] and unsanctioned needle exchanges.[8] In New York City, where seroprevalence among IVDUs reached about 60 percent,[9] cross-sectional and ethnographic studies report decreased needle sharing, increased needle cleaning, and increased demand for sterile needles on the streets.[10–13]

In San Francisco, one study found no change in needle sharing for cross-sectional samples drawn in 1985 and 1987,[14] while in three other studies IVDUs self-reported some decrease in sharing.[15–17] We report changes in needle sharing behavior for two samples of IVDUs entering drug detoxification programs in San Francisco for successive time periods from 1986 to 1988, and for two retrospective cohorts repeating treatment during the study period. We also evaluated correlates of needle sharing behavior.

Methods

Study respondents were IVDUs consecutively entering outpatient drug detoxification clinics (San Francisco General Hospital and Haight Ashbury Free Medical Clinic) from April 1986 through September 1988 (N = 7,660). Participants were interviewed on admission concerning demographics, drug use, drug treatment, and the number of needle sharing occasions for the 30-day period preceding admission to treatment. To evaluate change over time, the data were partitioned into consecutive six-month calendar periods, giving a total of five time blocks. The proportion of participants reporting any needle sharing was compared across time periods. The two largest cohorts of treatment repeaters within non-adjacent six-month periods were identified in 1986–87 (n = 303), and in 1986–88 (n = 205).

Logistic regression modeling was applied to identify correlates of needle sharing, using only the first admission for each individual during the study period (n = 5,610). The outcome variable was number of needle sharing occasions in the past month, coded dichotomously to reflect *any* sharing versus *no* sharing. Sex, age, education, ethnicity, cocaine use, number of prior admissions to drug treatment (<3 admissions or 3+ admissions), and time period (coded 1–5) were entered as predictors. Since route of administration was not known for cocaine, this variable reflects cocaine administered by smoking, injection, inhalation, and other routes.

Results

Demographic characteristics reported here reflect only the first admission for each individual within each clinic (n = 5,916). For both clinics combined, most admissions (92 percent) were for heroin use. The separate clinic samples differed in terms of age, ethnicity, education, and drug of choice (Table 1).

For all admissions to both clinics (N = 7,660), the proportion of cases reporting any needle sharing decreased at each successive time period, from 50 percent at Time 1 (April-September 1986) to 28 percent at Time 5 (April-

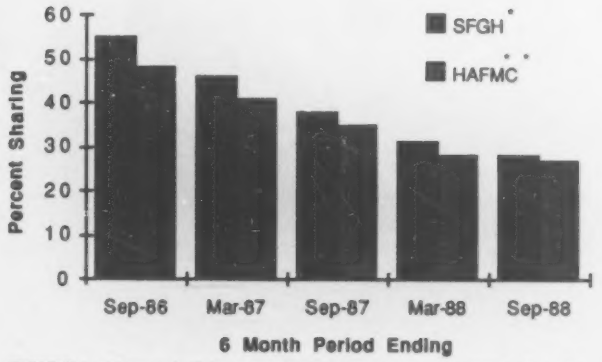

FIGURE 1—Changes in Self-reported Needle Sharing among IVDUs Entering Two San Francisco Outpatient Detoxification Clinics, 1986–88

September 1988). The data for each clinic separately are presented in Figure 1.

Self-reported needle sharing also decreased in individuals seen more than once. For the cohort entering treatment in both 1986 and 1987, the proportion of needle sharers decreased from 52 percent to 35 percent. For the cohort entering treatment in 1986 and 1988, the proportion of sharers decreased from 47 percent to 23 percent.

Frequencies for variables included in the model predicting any needle sharing are given in Table 2, together with a summary of logistic regression results. Four variables predicted needle sharing:

- IVDUs entering treatment at later time periods were less likely to report needle sharing;
- IVDUs reporting any use of cocaine were more likely to report needle sharing;
- older IVDUs were less likely to report needle sharing; and
- Blacks reported less sharing than did Whites.

Discussion

Self-reported needle sharing decreased over time for the total sample (N = 7,660), for each individual clinic sample, for treatment repeaters, and in logistic modeling which considered only first admissions. Consequently, the observed decrease in needle sharing is not likely due to unique characteristics of individual clinic samples, or to the presence of treatment repeaters in samples selected for univariate analyses.

Self-report bias could account for these results. We asked a convenience sample of 20 methadone detoxification participants, after admission to treatment, about underreporting of needle sharing at the time of admission. Most thought that underreporting would occur, but for reasons of social desirability rather than entry into treatment, which implies that these data reflect a lower boundary rather than "true" needle sharing. Collecting data within drug treatment programs also limits generalizability to a large non-treatment population. Of the estimated 16,000 IVDUs in San Francisco,[18] only 5,000 entered treatment in 1987.

The finding of decreased needle sharing behavior over time indicates that many San Francisco IVDUs are reducing risk of HIV infection by modifying needle sharing behavior. These risk-reduction practices, together with increased needle cleaning previously reported among San Francisco IVDUs,[14,19] may account in part for the decrease and leveling of seroconversion in this population from 7 percent per year in 1985 to an estimated 2.4 percent currently.[20] Nevertheless, 30 percent or more of San Francisco IVDUs still admit to the

*Sample includes only the first admission into either clinic, for each individual, during the study period.
**Percentages reflect proportion of cases in each category who reported needle sharing.
+Adjusted odds ratios.
++For continuous variables, sign gives direction of relationship with needle sharing. For dichotomous variables, odds ratio reflects change in units from left to right.

behavior that most effectively facilitates the spread of HIV, signaling the need for a second wave of innovative and aggressive AIDS prevention to include greater emphasis on cleaning needles with bleach, increased collaboration between members of the IVDU subculture and public health workers, and the use of multiple intervention strategies.[21,22]

ACKNOWLEDGMENTS

The authors gratefully acknowledge the conceptual contributions of Norman Hearst, MD, and John Watters, PhD. The efforts of Wayne Clark, PhD, Kit Riley, LCSW, and John Newmeyer, PhD, were instrumental in different aspects of data collection. We sincerely appreciate the participation of staff and patients at the San Francisco General Hospital Substance Abuse Services, and at the Haight Ashbury Free Medical Clinic.

Some of the data included in this manuscript were presented at the V International Conference on AIDS, Montreal, June 1989 (Abstract Th.D.P.34).

This work was supported by NIMH and NIDA (Contract no. MH42459), and the AIDS Clinical Research Center, University of California, San Francisco.

AAP Report Examines Medicaid State Reports for 1988

Children in the United States account for about half of Medicaid recipients, but only one-fifth of Medicaid expenditures, according to a recent report issued by the American Academy of Pediatrics. In the analysis, entitled *Medicaid State Reports, Fiscal Year 1988*, AAP says that only 20 percent of children eligible for Medicaid received services under the Early and Periodic Screening, Diagnosis, and Treatment (EPSDT) preventive care program—a decrease of 13 percent from the pervious year.

The compilation of Medicaid reports examines state, regional, and national statistics on children's health, infant mortality, prenatal care, medicaid recipients and cost, and Medicaid program characteristics. The reports (also generated in 1982, 1984, and 1987) assist policy-makers and analysts in assessing their state's Medicaid program in comparison with others.

Reports for single states are available from the APP at no charge. Complete sets of reports for 49 states and the District of Columbia are available for $15 per packet. Individual or complete reports can be obtained by contacting the American Academy of Pediatrics, 141 Northwest Point Blvd., P.O. Box 927, Elk Grove Village, IL 60009-0927. Tel: Carol Kolbaba, 708/981-7945, or Michelle Zajac, 708/981-7389.

Meeting the Needs for Health Services of Persons with Mental Retardation Living in the Community

PAULA M. MINIHAN, MSW, MPH, AND DEBORAH H. DEAN, MSPH

Abstract: Adequate health services are critical to the success of efforts to maintain persons with mental retardation in the community, yet information concerning the health status of this population is in short supply. This paper presents the results of a survey of 333 mentally retarded persons randomly selected from a population of 1,333 such individuals living in community settings. Almost two-thirds had chronic conditions requiring medical intervention. The top five conditions in terms of prevalence were neurologic, ophthalmologic, dermatologic, psychiatric-emotional, and orthopedic. The majority of conditions were being managed appropriately in the community health system. A substantial proportion can be managed by primary care physicians with limited specialty involvement. For almost 60 percent of clients with conditions requiring home treatments on an ongoing basis, however, service gaps were identified. Other problems included the reluctance of some providers to accept Medicaid, and the inability of some clients to cooperate with medical examinations. (*Am J Public Health* 1990; 80:1043–1048.)

Introduction

Adults and children with mental retardation have the same needs as other individuals for preventive health care, episodic care for acute illness, and ongoing care for chronic medical conditions. They often have chronic conditions, physical disabilities, and sensory deficits that are associated with their mental retardation and require specialized services. Some may have acquired conditions, e.g. contractures, related to suboptimal medical management.[1]

Ensuring adequate health services to manage these needs is critical to the success of efforts to maintain persons with mental retardation in the community, yet information concerning the population living in community settings and their requirements for health services is in short supply. The decentralized nature of the community system and the variety of living arrangements which it supports—ranging from sheltered housing with on-site supervision to assistance to persons living with their families or living independently—make it difficult to conduct survey research which depicts the overall population.

National data are available which describe the population living in staffed residential facilities in the community.[2] Comparable data describing retarded persons living with their families or living independently are not available although this is a larger population.

Published studies of the health needs of persons with mental retardation living in community settings report that these individuals have significant health problems,[3–5] but they may be biased toward individuals with the most complex medical conditions. None are based on the experiences of randomly selected subjects, a factor which is of concern given the heterogeneous nature of this population. Two of the published studies are also based on the experiences of a limited number of subjects, most of whom had been previously institutionalized, a factor generally associated with a poorer health status.

Studies of the prevalence of medical conditions among mentally retarded persons living in institutions also report that these individuals carry a burden of chronic disease which is greater than that in the general population.[6–8] Studies describing the health status of institutionalized populations, however, may not be applicable to the population living in the community, particularly to those who have never been institutionalized.

The present study sought to eliminate these potential sources of bias by surveying the health needs of a large sample randomly selected from a population of persons with mental retardation living in a range of settings in the community. Only one-third had been institutionalized previously. Information is provided concerning the prevalence of chronic conditions among these individuals and their concomitant requirements for physician, allied health, and home health services.

Methods

Sample

The study population universe was composed of 1,333 individuals with mental retardation who were receiving services in the community system administered by the Massachusetts Department of Mental Health/Division of Mental Retardation in southeastern Massachusetts. All clients were receiving active case management services and most were receiving additional services including residential and day program services. A sample of 350, stratified by area, was randomly selected for study. Seventeen individuals who did not meet eligibility criteria were excluded: seven lived in other regions, eight had withdrawn their request for services, one was determined not to be mentally retarded, and one was living in a public institution. The final sample consisted of 333 clients.

Data Collection

Data were collected by a client-specific questionnaire that was completed for each client by his or her designated service coordinator. The survey covered a 12-month period. Following training sessions supplemented by a reference manual, the questionnaire was completed primarily from the clients' record which includes their individual service plans. Regulations require a medical assessment for each client soon after the initiation of services and reviewed annually thereafter, and an annual medical assessment that includes a physical examination with a gynecological examination for women. The record also contains the service coordinator's quarterly progress notes which document events relevant to

the client's major health and other service needs. If the information requested in the questionnaire was not available in the record, the client's program staff or family was contacted to obtain it. Completed questionnaires were obtained for all of the 333 clients in the sample.

Data concerning the prevalence of chronic conditions were validated as follows: a 16 percent random sample was selected from the group who had been institutionalized. Their medical records in the institution were reviewed and compared with the information in this survey. In addition, for seven clients, medical assessments had been completed by their physicians 18 months earlier in another survey conducted by these authors;[7] this information was similarly compared with the survey information.

Data Analysis

Data related to clients' background, demographic characteristics, extent of need for health services, and health service utilization were analyzed using the Statistical Package for the Social Sciences (SPSS). Responses to open-ended questions were content analyzed according to pre-selected categories. In order to determine the adequacy of service utilization, several measures were taken. The project's advisory committee, an interdisciplinary group of professionals with expertise relative to mental retardation, delineated the constellation of physician and home health services that should be available to mentally retarded persons in the community. The services received by a client were judged to be adequate if the client was being seen by the appropriate type of provider given the nature and severity (i.e. level) of the client's medical condition. The analysis of physician services involved an additional step: a physician review panel—composed of an internist/family practitioner in private practice, a family practitioner in a community health center, and an internist practicing in a state residential facility for the mentally retarded—reviewed the client's medical conditions and noted if the current provider was adequate.

Determining Need for Physician and Allied Health Services—The project's advisory committee decided that each client should have an age-appropriate primary care physician (internists for adults, pediatricians for children, family practitioners for either). Specialists, when needed, would provide supplementary care or care in partnership with the primary care physician. Adequate primary care for women included the provision of routine gynecological examinations and pap smears on a regular basis. To quantify the need for specialty physician services, classifications were developed which categorized the clients' chronic medical conditions by level. Each level corresponded to the type of medical provider most appropriate for managing the condition in the community.

- *Level 1 conditions* are managed solely by the client's primary care physician, or by the primary care physician with specialty back-up on an infrequent basis; i.e. less than once a year. For some Level 1 conditions, the extent of the specialist's role might be a one visit consultation for diagnostic purposes with subsequent management provided by the primary care physician. Level 1 care also includes preventive health care, and care for acute episodes of illness. Examples of Level 1 conditions include: occasional or borderline hypertension, and adult onset diabetes with no medication required.
- *Level 2 conditions* are characterized by increased specialty involvement. They are managed by the primary care physician with specialty back-up at least once a year or by a specialist solely at least once a year. Examples of Level 2 conditions include: recurrent otitis media, and peptic ulcer.
- *Level 3 conditions* are managed by a specialist solely whose involvement is ongoing (i.e. several visits a year). Examples of Level 3 conditions include: brittle diabetes in poor control, and uncontrolled grand mal seizures.

The physician review panel reviewed the data provided concerning chronic conditions and determined the following for each condition: 1) the system (e.g. cardiovascular, neurologic) which was involved; 2) whether the condition described was Level 1, 2, or 3; and 3) if care by a specialist was indicated, whether the client was seeing an appropriate kind of specialist. If a specialist was not being seen when necessary, or if an inappropriate type of specialist was following the condition, the service pattern was judged to be inadequate. The panel also reviewed information concerning services provided by allied health professionals and determined whether the allied health professional being seen was an appropriate provider for the condition described.

Determining Need for Home Health Services—Acknowledging that some clients have medical conditions that require ongoing care and treatment at home, the survey assessed the adequacy of home health services in a similar manner. The advisory committee began with the premise that many home health treatments can be safely provided by lay persons including parents, on the condition that the provider is trained and periodically monitored by a nurse. To quantify the need for home health services, the advisory committee developed a list of 16 home health needs commonly encountered in this population and categorized each need by level; each level carried with it a requirement for a specific degree of nursing involvement.

- *Level I needs* are supervised by a nurse who visits the residence on an as needed but regularly scheduled basis. Examples: prescribed topical skin treatments (e.g. lotions), weight control programs, and prescribed eye drops.
- *Level 2 needs* are supervised by a nurse who visits the residence at least once a day. Examples include: medications which require monitoring because of concerns about large dosages or potential side effects; and brittle diabetes, requiring daily insulin injections, urine tests, and diet precautions.
- *Level 3 needs* are attended to solely by a nurse. Examples include: specific nursing treatments (e.g. shunt care), catheter care, and suctioning.

The home health services section of the questionnaire included the list of home health needs developed by the advisory committee. After designating which of these needs applied to their client, service coordinators were asked to describe the client's current care pattern by indicating who attended to these needs.

Direct care by a nurse was considered an adequate care pattern for needs at all three levels. No care or care by the client alone or by an untrained, unsupervised lay person were considered inadequate patterns of care at all three levels.

Results

Sample Characteristics

As shown in Table 1, the sample closely resembled the study population in terms of sex, age, and prior institution-

TABLE 1—Distribution of Population and Sample by Age, Sex and Prior Institutionalization

Characteristics	Population (N = 1333)	Sample (n = 333)
Sex	%	%
Male	54.0	51.7
Female	45.8	48.4
Unknown	0.2	0
Age (years)		
0–17	5.2	5.4
18–21	11.0	10.8
22–44	61.3	61.6
45–64	19.6	20.4

alization. The largest proportion of the study sample (39.3 percent) lived with their families; 36 percent lived in residential programs supervised by the state Department of Mental Health; 5.7 percent in nursing homes, and 3.6 percent in rest homes. Almost 9 percent lived independently with minimal or no supervision. The remaining clients (6.6 percent) lived in various settings including supervised residences for individuals with psychiatric conditions, and family-arranged foster homes. Sixty-six percent had never been institutionalized in a public facility for the mentally retarded. Sixteen percent lived in residential settings with nurses on site and received all or most of their health services, including physician services, within their facility. The remainder, who lived either in family situations, in residences with non-medical staff, or independently, were expected to obtain their health services from providers serving the general population.

Medicaid was the sole source of payment for health services for 65 percent; an additional 14 percent received both Medicaid and Medicare, and 5 percent were Medicare beneficiaries solely. Almost 11 percent were insured by commercial or private insurers; one percent reported "other" payment sources, and for 3 percent the payment source was unknown. Less than 3 percent reported no health insurance coverage.

Care by Primary Care Physicians—Eighty-seven percent of the sample were reported to have a regular physician (who knows the client, manages overall medical care and refers to specialists as needed). For clients younger than age 22, 49 percent were being seen by a pediatrician and another 30 percent by an internist. For older clients, 47 percent were being seen by an internist and 36 percent by a family or general practitioner. The clients who did not have regular physicians tended to be living with their families (50 percent) or living independently (27 percent).

Only 40 percent of the women ages 18 and older were known to have had a gynecological examination provided by either her primary care physician or by a gynecologist within the three-year period preceding the survey. In written comments, 7 percent of women ages 18 and older were noted to have refused gynecological examinations or to exhibit behaviors that made gynecological examinations impossible.

Care by Specialty Physicians—Sixty-two percent of the clients were judged to have one or more chronic medical conditions serious enough to warrant ongoing medical intervention: 30 percent with one condition, 14 percent with two conditions, 12 percent with three conditions, and 5 percent with four or more conditions. Eight-four percent of the chronic conditions reported were being managed by physicians, and 16 percent were managed by allied health professionals (e.g. podiatrists).

The reported prevalence of chronic conditions by systems for all clients is shown in Table 2. In terms of prevalence, the top five types of conditions were neurologic, ophthalmologic, dermatologic, psychiatric-emotional, and musculoskeletal or orthopedic. The high prevalence of neurologic conditions reflects primarily seizure disorders (16 percent). As shown in Table 3, the distribution of conditions by system and level indicates that while many of the conditions were judged manageable by a primary care physician, a substantial amount of specialty involvement is called for. Among the five most prevalent conditions, dermatologic conditions were primarily Level I conditions, while the majority of the neurologic, ophthalmologic, psychiatric-emotional and orthopedic conditions were Level 2, requiring a partnership between the primary care physician and a specialist, or Level 3, needing the ongoing involvement of a specialist. Looking at all conditions together, nearly half were judged to be Level 1, 14 percent were Level 2 and almost 40 percent were Level 3.

The allied health professionals named most frequently as managing chronic conditions were podiatrists who managed 9 percent of the conditions, and optometrists who managed almost 5 percent.

Among the previously institutionalized clients, who had been living in the community an average of 4.6 years, 20 conditions were reported in their institutional records; 13 of these conditions were reported in this survey. Of the seven conditions not reported, two involved hearing loss, one was a refractive error (good vision with glasses), two were cardiac murmurs, one was mild spastic cerebral palsy and one was hypothyroidism. Six new conditions were reported; of these, two were skin irritations requiring topical treatments; the others were a fungal infection of the nailbed, anxiety treated with medication, high blood pressure, and a heart murmur.

Among seven clients about whom physicians had provided information 18 months earlier,[7] 18 conditions were

100% (325)	47 (152)	14 (46)	39 (127)

reported by their physicians, 14 of which were reported in this survey. Of the unreported conditions, three were ophthalmologic (hyperopia/esotropia, light esotropia, and immature cataracts) and one was dermatologic (acne). Two new conditions were reported: chronic constipation and osteoporosis.

Adequacy of Service—As Table 4 indicates, 92 percent of conditions managed by physicians and 89 percent of conditions managed by allied health professionals were judged to be adequately managed. Information concerning conditions for which service utilization was judged to be inadequate is shown in the Appendix.

Need for Home Health Services—Fifty-seven percent of clients were reported to have a chronic condition which carried with it a need for ongoing care and treatment at home. For all clients, level of care was judged to be Level 1 in 28 percent, Level 2 in 27 percent, and Level 3 in 2 percent. The reported prevalence of home health needs is shown in Table 5. Clients who had been cared for by a nurse were found to be receiving services from a variety of agencies, with the highest proportion (15 percent) receiving services from nurses employed by their departmentally contracted residential or day program vendor. Only 3 percent were receiving services from generic home health agencies such as the Visiting Nurses Association.

Of all clients reported to have home health needs, 30 percent were judged to be receiving adequate care while 61 percent were receiving inadequate care. Another 9 percent were receiving "mixed" nursing services; some of their needs were met via an adequate service pattern while other needs received an inadequate pattern of care. For 59 percent of clients with home health needs, licensed nurses were not involved at all, either as direct care providers or as trainers and supervisors of direct care providers.

Catheter care	0.6 (± 0.4) (2)
Suctioning	0.3 (± 0.3) (1)

*Some clients reported more than one condition requiring home treatment.

Other Problems Obtaining Health Services—The data suggested that some clients faced additional problems in obtaining health services. The most frequently cited barrier was a financial one. Of the 267 clients who were Medicaid recipients, almost one-fourth reported one or more instances during the survey period when a health provider refused or was reluctant to serve them because the source of payment was Medicaid.

Characteristics of the clients themselves on occasion created barriers to care. One such characteristic is the ability to cooperate with medical examinations and treatments. For 20 percent of clients, examinations and treatments were able to be completed only when supportive measures were taken to prepare the client, e.g., pre-medication or pre-visits for desensitization purposes. For eight clients, examinations and treatments were able to be completed only when extraordinary measures, such as physical restraints or general anesthesia, were taken. Some clients, while generally cooperative with medical treatment, were said to require supportive measures for specific examinations, e.g. gynecological.

Discussion

It is widely assumed that individuals with mental retardation carry a heavy burden of chronic disease requiring an extensive and highly specialized array of medical services that may be difficult to obtain in the "generic" community health care system. Several studies support this assumption.[3–8] This study, while confirming the relatively high prevalence of chronic illnesses requiring medical intervention, indicates that the vast majority of these conditions

for the group studied can appropriately be managed and are being managed within the community health care system. Further, the study shows that about half of these conditions do not require the services of specialty physicians but can be managed by primary care physicians. Almost 90 percent of clients were connected with a primary care physician who served as their "regular doctor," indicating that they have obtained a portal of entry to the health care system that eludes many individuals in the general population. The findings concerning primary care for women were not as sanguine. Less than 40 percent of the women were known to have had a routine gynecological examination within the three years prior to the survey, thereby missing an important opportunity for prevention and early detection of disease. Given the lack of agreement within the medical community as to the recommended frequency of preventive gynecological examinations for the general population, Massachusetts regulations calling for yearly gynecological examinations for women appear overly rigid. Nonetheless, the provision of gynecological services for women with mental retardation appears to be poorly implemented.

The major service gap identified by this survey concerned the provision of home health care, a subject that has received little attention relative to the mentally retarded. In the judgment of the advisory committee, the optimum management of home health needs in the community service system calls for the involvement of a nurse, who would function most often as a trainer, supervisor, and monitor of lay care givers, and not as a direct care provider. This approach arose from the belief that any home health system established for this population must address the fact that most of these individuals cannot attend to their own health needs. The system must also be designed to accommodate the range of care givers in the community system who have taken on this responsibility. In particular, it must address the fact that staff in many community residential programs are young, inexperienced, and have a high turnover rate. Almost 60 percent of clients with home health needs in the sample studied had not had a nurse involved in their care at all. The remainder of clients had been seen by a nurse but in many instances the nurse acted as a short-term direct care provider and did not function in the expanded role specified by the advisory committee. Generic home health agencies are a potential source of nursing support. Less than 3 percent of the sample receiving nursing services, however, received their care from such agencies. Current regulations governing the financing of home health care by third parties may restrict the availability of services to the resolution of acute conditions and exclude management of the long-term chronic conditions seen among this population. If generic home health agencies are not a realistic source of services for mentally retarded persons in the community system, serious thought must be given to developing alternative ways to provide this essential health supervision.

The other major area of concern involved financing. At the time of the survey, the Commonwealth of Massachusetts offered generous Medicaid benefits, as compared with other states. Yet almost a fourth of the clients reported instances during the survey period when a provider refused or was reluctant to serve them because the payment source was Medicaid. Currently anticipated deep reductions in publicly financed health benefits in Massachusetts and elsewhere will undoubtedly exacerbate these problems. Such changes could place the health of retarded persons at risk. The heavy dependence of this population on publicly financed health programs in part results from the fact that mentally retarded persons as a group are generally denied access to generic health insurance programs because they are assumed to be in need of expensive and complex health services.

Sterling Garrard suggested in 1983 that the level of consumption of health services by persons with mental retardation living in the community is determined by the proportionate mix of three sub-groups.[9] The first is a low consuming group, probably comprising a sizable minority of the population, whose major service requirements are for primary care with an emphasis on health maintenance. The second is an intermediate consuming group, also estimated as a sizable minority, where increased morbidity necessitates more frequent medical encounters. The third group is a high consuming group estimated to be a small minority of the population. Their increased utilization of health services is attributable to severe chronic medical conditions. Their major service requirements are for primary care frequently supplemented by specialty consultations.

The findings of this study support Garrard's suggestion. A recent study of state Medicaid expenditures, which found that the disabled with mental retardation as their primary disability did not have higher than average expenses in most states, also supports Garrard's contention.[10] It is possible that previous studies reporting significant health problems among persons with mental retardation may have been weighted toward Garrard's high consuming group while the two latter studies included individuals from all three groups. Further research is imperative to confirm or challenge these findings; such data are critical to efforts to advocate that persons with mental retardation have access to the health care organizations and insurance programs available to the general population.

Some underreporting of chronic medical conditions undoubtedly occurred in this study. The need to employ respondents who were comparable for all subjects despite their different living arrangements led to the decision to select the service coordinators as respondents despite the fact that they might not have the same first-hand knowledge of the client's health status as the client's physicians, parents, or residential program staff. To minimize underreporting, service coordinators were instructed to report all medical conditions noted in the client's record which contains the report of the client's most recent physical examination (in all cases completed by a physician within the past year) as well as treatment plans to address the client's major needs. If the record information was incomplete, the client's family or residential program staff were contacted. In addition, all prescribed medications used by the client within the past 12 months were noted and checked to ensure that each was linked to a medical condition reported in the questionnaire. These two checks showed that from 65 to 78 percent of all chronic conditions were reported in the record, and that unreported conditions were predominantly Level 1, the least serious conditions.

A second potential source of underreporting was the study's focus on individuals in the community who were receiving services from the state mental retardation agency. There are mentally retarded individuals in every community who are not known to public agencies, although their numbers are difficult to estimate. It is generally understood, however, that those individuals in the greatest need of services are the most likely to turn to the state agency for assistance. For adults, it is unlikely that individuals who were not being served by the state agency would have a higher

prevalence of conditions than clients in this study. The needs of individuals under age 22, however, may be underrepresented, since in Massachusetts, the Department of Education and not the Department of Mental Health, is the primary provider of services for persons with mental retardation under age 22. The small proportion of children under 18 years of age in our survey reflects this fact.

Finally, it is important to note that good health care comprises more than simply obtaining the services of appropriate physicians, allied health professionals, and home health providers. Quality of care considerations, while very important, were beyond the scope of this survey. Some responses also indicated that many clients had encountered particular types of problems when seeking health care, including, at times, negative attitudes toward or poor interpersonal skills with mentally retarded patients. Future research efforts should attempt to describe more completely these and other barriers to obtaining health services in the community. Preventive health services and the availability of ancillary and rehabilitative services such as physical therapy and adaptive equipment services deserve particular attention.

APPENDIX

Medical Conditions with Inadequate Service Utilization among Mentally Retarded Clients

Physician Services

- One Level 1 skin condition was managed by a psychiatrist; dermatologist recommended.
- One Level 2 cardiovascular condition was managed by a general practitioner; cardiologist recommended.
- One Level 2 psychiatric/emotional condition was managed by a general practitioner; psychiatrist recommended.
- One Level 3 eye condition was managed by an optometrist; ophthalmologist recommended.
- One Level 3 eye condition was managed by an ENT; ophthalmologist recommended.
- One Level 3 neurological condition was managed by a neurologist; neuropsychiatrist (behavioral neurology) recommended.
- One Level 3 neurological condition was managed by a psychiatrist; neurologist recommended.

Allied Health Services

- Two eye conditions were managed by optometrists; recommended provider types were ophthalmologists.
- Three skin conditions were managed by podiatrists; recommended provider types were dermatologists.
- One gastrointestinal condition was managed by a homeopath; recommended provider type was a gastroenterologist, possibly with consultation from a psychiatrist.

ACKNOWLEDGMENTS

The authors wish to thank the members of the advisory committee, chaired by Cynthia Hardy, Assistant Superintendent for Community Services at the Paul A. Dever School, for contributing so much of their time and energy to this project. Members included: Richard DeTucci, Florence Finkel, Herbert Gilmore, MD, Susan Wareing Gosselin, Debra Grzywacz, John Nay, Jeanne Reed, Mark Sanderson, Reuben Schonebaum, PhD, Daniel Shea, Michele Slavin, Philip Tully, and Stephen Williams. We also wish to thank the members of the physician review panel, Benedict Duffy, MD, Appleton Mason, MD, and Robert Wesselhoeft III, MD, MPH, for their efforts. Finally, we wish to acknowledge the special contribution of the Department of Mental Health service coordinators throughout southeastern Massachusetts who carefully and patiently completed the questionnaires and provided the primary data base for the project.

Funding for this project was provided in part by the Paul A. Dever School of the Massachusetts Department of Mental Health.

Some of these data were presented at the 113th annual meeting of the American Public Health Association in Washington, DC 1985.

NIH Consensus Statement on Surgery for Epilepsy now Available

A National Institutes of Health (NIH) consensus development statement on Surgery for Epilepsy has been developed by a panel of experts who considered scientific evidence at a Consensus Development Conference held March 19–21, 1990 at NIH.

Single copies of the report, or the two-page summary, may be obtained from: William H. Hall, Director of Communications, Office of Medical Applications of Research, NIH, Building 1, Room 259, Bethesda, MD 20892. Tel: (301) 496-1143.

Homeless and Housed Families in Los Angeles: A Study Comparing Demographic, Economic, and Family Function Characteristics

David Wood, MD, MPH, R. Burciaga Valdez, PhD, MHSA, Toshi Hayashi, PhD, and Albert Shen, MPH

Abstract: We studied 196 homeless and 194 housed poor families in Los Angeles, California to gain an understanding of events that precipitate family homelessness. Both homeless and housed poor mothers averaged 29 years old and were accompanied by two or three children. Three-fourths of both the homeless and housed families had income below the poverty level, and both groups expended almost two-thirds of their income on housing. Mothers in homeless families more commonly reported spousal abuse (35 vs 16 percent), child abuse (28 vs 10 percent), drug use (43 vs 30 percent), or mental health problems (14 vs 6 percent) and weaker support networks. Homeless mothers more commonly came from homes where their parents abused drugs or alcohol (49 vs 34 percent) or more commonly lived outside the home or in foster care (35 vs 25 percent). Homelessness was reported as due primarily to economic pressures of housing costs, but personal and family problems frequently played a contributing role, especially for single parent families. Burdens of increasing housing costs and family dysfunction among housed poor families place many at risk for homelessness. (*Am J Public Health* 1990; 80:1049–1052.)

Introduction

Families make up over one-third of the homeless nationwide, and in many large cities (e.g., New York, Philadelphia, Portland) families represent the majority of the homeless population.[1] Los Angeles has approximately 35,000 to 50,000 homeless persons, about one-third of whom are members of homeless families.[2] The growth of the homeless family population has been attributed to increasing poverty among families combined with rising housing costs[3] and family dysfunction.[4–6]

A number of studies indicate that changes have occurred in the composition of the homeless family population over time and that important geographic variations exist.[1,7–10] Yet, with the exception of one study in Boston,[4] only descriptive studies of the homeless family population are available. To shed more light on the composition of homeless families and gain a better understanding of the precipitating events of homelessness among families, we surveyed 196 homeless families in shelters and compared them to 194 housed, poor families in Los Angeles, California. The health status of homeless and housed children was also assessed and those comparisons are presented elsewhere.[11]

Methods

Homeless families (n = 196) and a comparison group of stably housed, poor families (n = 194) were interviewed during March 1987 through early 1988 in Los Angeles, California. From a universe of 23 shelters serving families in Los Angeles, homeless families were sampled from the 10 largest and busiest shelters. These 10 shelters received 80 percent of all family shelter referrals in Los Angeles during the three months preceding the study. Interviewers visited each shelter at least weekly during the interview period and sampled families from among those who had come to the shelter within the past week. In the five smaller shelters (less than 10 families) a complete sampling of the new families was attempted. In the five larger shelters every other new family was selected for an interview. If after two attempts we failed to locate a family, we approached the next family on the roster.

The housed, poor families were systematically sampled from families presenting to four welfare offices, selected on the basis of the geographic distribution of the "last stable address" of the homeless families. In the welfare offices we screened all presenting families and requested an interview from those who had lived in their current residence at least six months and had received welfare benefits continuously for at least one year. Of the 240 families we sought to interview, 46 refused to participate. There were no differences in age or ethnicity of the mothers who refused compared to the respondents.

Interview and Questionnaire

Structured interviews were conducted with the mothers by trained interviewers and lasted approximately 45 minutes.

Families were categorized as female, single-parent or two-parent families based on whether the mother reported that she was currently with an adult male partner. The mothers were asked if they had been abused in their current or most recent significant relationship, if they or their partner abused drugs or alcohol, and if they or their partner had a history of hospitalization for mental illness. Mothers also were asked if, in her family of origin, there was a history of family violence, drug or alcohol abuse, or mental illness. The quantity and quality of maternal social supports were assessed by documenting the total number of persons the mother could rely on for support, the ages of the supports, and the mother's relationship to the supports.

Family income was a summation of the total income contributed from all family members over the past year and was further assessed by source. The percent of income expended on housing was derived by dividing reported rent and utility expenditures by the average monthly income. For homeless families, we asked them to report the rent and utility costs at their last stable residence (defined as the family having their own place for at least two months' duration).

Housing histories included the number of moves over the past five years and the types of living situations experienced (doubled up with strangers, living in a hotel or motel, living in a car or on the street). Homeless families were asked to describe the events leading to their loss of housing. For each

narrative, two raters independently identified a primary precipitating event which were then grouped into five categories: 1) *Economic*—such as job loss or loss of AFDC (aid to families with dependent children) grant income; 2) *Housing-related*—such as eviction, failure to pay rent, conversion, or demolition; 3) *Marriage or family relationship* problems; 4) *Violence* and/or drug related; 5) *Natural disaster*. When multiple events were described, the rater sought to identify the initiating or underlying event. For example, where income loss lead to eviction the primary event was classified as "income loss."

Analysis

The homeless and housed samples were compared using simple comparison of means and proportions and two-tailed t-test and Chi-square analysis. We report 95 percent confidence intervals for the differences in means and proportions. Multiple regression as used to test each comparison while controlling for potentially confounding factors of race, maternal education, child sex, child age, and family structure. The qualitative results remained unchanged, so we report the unadjusted comparisons for simplicity.

Results

Demographics and Family Structure

The majority of homeless and housed mothers in our sample were Black, and averaged 29 years of age (Table 1). A larger proportion of the homeless mothers were White. Homeless mothers reported larger families and were less likely to have graduated from high school. More of the homeless families were headed by two parents and and more of the homeless couples than housed couples had been together for over one year (Table 1).

Family Problems and Maternal Social Supports

Homeless mothers reported more spousal abuse and drug abuse by their mates and were more likely to have had a child abuse report opened on the family and more likely to have personally required hospitalization for mental illness

TABLE 1—Demographic Characteristics of Homeless and Housed Women and Families

Characteristic	Homeless Families (n = 196)	Housed Families (n = 193)	Difference of Homeless-Housed (95% confidence interval)
Maternal ethnicity (%)			
Black	57	70	−13 (−22, −4)
Non-Latino White	30	15	15 (7, 23)
Latino	8	11	−3 (−9, 3)
Other	6	4	2 (0, 4)
Percentage of mothers with high school diploma or some college	57	72	−15 (−24, −6)
Percentage of families with two parents (versus single-parent, female-headed)	47	38	9 (1, 19)
Percentage of two-parent families together more than one year	83	62	21 (12, 30)
Mean number of children per family	2.7	2.3	0.4 (0.1, 0.7)
Mean Maternal age	29.5	29.0	0.5 (−1, 2)

TABLE 2—Percentage of Mothers Reporting Violence, Drug or Alcohol Abuse, Criminal Involvement, and Mental Health Problems

Family or Personal Problem Reported	Homeless Families (n = 192)	Housed Families (n = 190)	Difference of Homeless-Housed (95% confidence interval)
Violence			
Mate abuses mother	34	16	16 (9, 25)
Mate involved in criminal activity	29	20	9 (0.4, 18)
Social service file opened for child abuse or neglect	28	10	18 (14, 22)
Drug Alcohol Abuse			
Mate abuses alcohol or drugs	43	30	13 (3, 23)
Mother abuses drugs	32	26	6 (−3, 15)
Mental Illness			
Mate has history of mental illness	15	11	4 (−3, 11)
Mother has history of hospitalization for mental health problem	14	6	8 (2, 14)

(Table 2). Both the homeless mothers and housed mothers frequently reported using drugs such as crack and heroin (32 percent and 26 percent, respectively).

A history of substance abuse and family violence were more often reported for the homeless mothers' own family of origin (Table 3). Over one-third of the homeless mothers reported being placed with relatives or in foster care as children compared to one-fourth of the housed mothers.

Two-thirds of homeless mothers named only one or no adult supports compared to one-half of housed mothers (Table 4). Fewer homeless mothers could rely on their parents for support, and they were more likely to rely on their own minor children for support than were housed mothers.

The single-parent homeless families reported many more relationship problems, such as drug abuse or violence than did the two-parent homeless families (means: 1.9 vs 1.2; Diff = 0.7, 95% CI = .39, .99). Single-parent homeless mothers also reported a mean of fewer adults in their network of social supports than the two-parent homeless families (1.3 vs 2.2, Diff = −.9, 95% CI = −1.34, −.37); and single-parent homeless mothers more often named their minor children as their primary supports than the two-parent homeless families. In contrast, the two-parent homeless families were very

TABLE 3—Percentage of Homeless and Housed Mothers Reporting Problems in Their Own Families of Origin

Problem Reported by Mother	Homeless Families (n = 195)	Housed Families (n = 189)	Difference of Homeless-Housed (95% confidence interval)
Mother's family of origin headed by single, female	40	47	−7 (−17, 3)
Mother's parents divorced or death of parent(s)	43	36	7 (−3, 17)
Mothers parent(s) abused drugs or alcohol	49	34	15 (5, 25)
As a child, mother lived with a relative or in foster care	35	25	10 (1, 19)
Mother was physically or sexually abused by parent(s)	31	21	10 (1, 19)

TABLE 4—Number and Type of Social Supports Reported by Homeless and Housed Mothers

	Homeless Mothers	Housed Mothers	Difference of Homeless-Housed (95% confidence interval)

Percentage of mothers reporting:			
1 or no adult support	66	48	18 (8, 28)
2 or 3 adult supports	26	36	−10 (−19, −1)
4 or more adult supports (n = 196, 194)	8	16	−8 (−14, −2)
Percentage of mothers naming own mother or father as a support (n = 196, 194)	31	65	−34 (−43, −25)
Percentage of mothers naming own child less than 18 years old as a support (n = 165, 167)	37	13	24 (15, 33)

similar to the two-parent housed families on measures of social support and family relationship problems.

Family Income, Housing Costs and Housing Histories

After adjusting family income for family size, over three-fourths of the families in both groups had incomes below the poverty level (in 1987 the poverty level for a family of three was $8940,[12] (Table 5). The income of the housed families came almost exclusively from welfare, whereas only 61 percent of homeless families were dependent exclusively on welfare (27 percent depended on the mother's or father's income exclusively or as a supplement to welfare, and 12 percent reported no income at all). Although AFDC was a primary source of income for homeless families, 43 percent reported losing or being removed from the welfare rolls during the past year.

Families in both the homeless and housed groups reportedly spent or had spent about two-thirds of their monthly income on rent and utilities (means: 67 percent vs 64 percent), and about one-fourth of each group had rent-to-income ratios above 80 percent (Table 5). Only about 15 percent of families in each group had rent-to-income ratios below 30 percent, the upper limit recommended by the federal housing guidelines.[13]

Homeless families reported long histories of housing instability, averaging 3.7 moves in the past year. Over 40 percent of the homeless families reported more than five moves in the past five years. During the past five years over half of the families had doubled-up with others (56 percent), three-fourths had lived in a hotel or motel (76 percent), and one-third had lived on the street or in a car (32 percent).

Although the housed families were chosen on the basis of their recent housing stability, many had experienced housing instability over the past five years. Almost two-fifths (39 percent) of the housed families reported that, sometime during the past five years, they had doubled up with strangers for housing, and almost one-fifth (19 percent) reported that they had lived in a hotel, motel, a car or a shelter. Thus, during the past five years, two out of five housed, poor families had experienced unstable living situations and one in five had been homeless.

TABLE 5—Reported Family Income, Rent Burden for Homeless and Housed Families

	Homeless (n = 196)	Housed (n = 194)	Difference of Homeless-Housed (95% confidence interval)
Mean family income	9,739	8,150	1589 (677, 2500)
Percentage of Families with income below poverty line	82	88	−6 (−13, 1)
Mean rent to income ratio	0.67	0.64	0.03 (−0.7, 0.13)
Mean number of moves over the past five years	5.9	2.3	3.6 (2.8, 4.4)

Precipitating Causes of Homelessness

The majority of homeless families (57 percent) described economic problems (i.e., job loss, loss of AFDC) or housing problems (i.e., eviction) as the primary precipitating cause of their homelessness; one-fourth described personal or family problems, such as a relationship breakup or estrangement from the extended family. Violence or drug problems were described as the primary causes of homelessness by 11 percent of the families. The distribution of precipitating events, however, was quite different for two-parent compared to single-parent homeless families. Two-parent families were more likely to cite economic or housing problems as precipitating events for homelessness than single-parent families (72 percent vs 48 percent; Table 6). Single-parent families were more apt to cite family problems as primary precipitant of homelessness than two-parent families (31 percent versus 16 percent).

Discussion

Previous surveys and earlier studies in various locales describe the homeless family population as predominantly composed of single-parent, female-headed families.[4,5,8,14] Yet almost half of our sample of homeless families was composed of two-parent families, most of whom had been together for over one year. Recent studies in Seattle, Portland, and other cities have similarly found approximately half of homeless families to be two-parent families.[1,7]

Previous homeless studies may have underestimated the proportion of two-parent families because they questioned only shelter directors or other "key" informants, or because two-parent families tend to falsely report themselves as single-parent families in order to qualify for services, including emergency shelter itself.[15] The high prevalence of two-parent families among homeless families has important implications for our public policy of family assistance. Due to categorical qualification criteria, two-parent families are less frequently eligible for family assistance programs such as

TABLE 6—Distribution of Reported Causes of Homelessness in Single-Parent versus Two-Parent Homeless Families

Percentage of Families Reporting Cause of Homelessness	Two-Parent-Families (n = 90)	Single-Parent Families (n = 97)	Difference of Two Parent-Single Parent (95% confidence interval)
Housing problems	34	28	6 (−7, 19)
Economic problems	38	20	18 (5, 31)
Family/relationship problems	16	31	−15 (−27, −3)
Related to drug use or violence	8	14	−6 (−15, 3)

Medicaid, the Homeless Family Assistance Program in California, and AFDC. These policies promote family separation and actually may precipitate homelessness.

Prior to becoming homeless, families were expending such high proportions of their income on housing that they had few resources remaining to meet other basic necessities such as food and clothing.[11] Our sample of stably housed families also reported equally high rent-to-income ratios of 60 to 80 percent, which puts them at great risk for housing loss; many reported doubling up or even experiencing short periods of homelessness over the past five years.

Millions of families nationally, including over two-thirds of all families on AFDC, expend over 50 percent of their family income on housing, and are severely rent burdened.[13,16–18] In almost all states, AFDC grants are well below the poverty level and in many states the entire AFDC grant does not reach the level of the lowest local Fair Market Rent.[19] AFDC grant levels must at least be raised to the federal poverty level, and should ideally be indexed to local fair market rents in order that families not expend more than 30 percent of their grant on housing.

Homeless families frequently experienced discontinuations of welfare assistance for administrative reasons rather than due to increased family income. This caused the family financial hardship and usually played an important role in their loss of housing. Nationwide, as many as 25 percent of welfare families annually experience administrative discontinuations without necessarily any change in their family income.[20,21] Welfare administrative procedures should be modified to promote rather than undermine the economic stability of fragile families and thereby prevent rather than precipitate their loss of permanent housing.

The stress of homelessness, pre-existing family problems, and weak support networks increase the likelihood that homeless families will not obtain access to our fragmented social service system. Family outreach services and comprehensive case management should be offered to assist homeless families to resolve family problems, secure permanent housing, and prevent future homeless episodes.[20,22] The outreach and case management services should include crisis intervention, assistance with program enrollment and benefit maintenance, family counseling, job training, and rehabilitation for drug dependence.

Several issues regarding our sampling strategy should be noted. We may have overrepresented newly homeless families and underrepresented families who have been homeless in the same shelters for longer periods. Further, due to logistical problems in the field and the limited resources of the study, the sampling in some shelters occasionally was reduced to a convenience sample of families. This limitation represents a common problem among published studies in this field.[23] Lastly, the housed, poor family sample may overrepresent Blacks and underrepresent Latinos compared to the overall AFDC population in Los Angeles; the difference resulted largely from our geographic selection of welfare offices to represent the homeless families' neighborhoods of origin.

In summary, the most common contributing factors to the loss of permanent housing among our sample of homeless families were high housing costs and family poverty. Interpersonal problems and social isolation also played a role in the loss of permanent housing, especially among the single-parent families. Housing costs continue to rise and family poverty is worsening, putting millions of American families at risk for losing permanent housing independent of the presence of interpersonal problems.

Racial Differences in Serum Cotinine Levels among Smokers in the Coronary Artery Risk Development in (Young) Adults Study

LYNNE E. WAGENKNECHT, DRPH, GARY R. CUTTER, PHD, NANCY J. HALEY, PHD, STEVE SIDNEY, MD, TERI A. MANOLIO, MD, MHS, GLENN H. HUGHES, PHD, AND DAVID R. JACOBS, PHD

Abstract: Cotinine was measured in the serum of nearly all 5,115 18–30 year old, Black and White, men and women participating in the Coronary Artery Risk Development in (Young) Adults Study, 30 percent of whom reported current cigarette smoking. Ninety-five percent of the reported smokers had serum cotinine levels indicative of smoking (>13 ng/ml). The median cotinine level was higher in Black than White smokers (221 ng/ml versus 170 ng/ml; 95 percent CI for difference: 34, 65) in spite of the fact that estimated daily nicotine exposure and serum thiocyanate were higher in Whites. The difference persisted after controlling for number of cigarettes, nicotine content, frequency of inhalation, weekly sidestream smoke exposure, age, gender, and education. A reporting bias and nicotine intake were ruled out as explanations for the racial difference suggesting that the metabolism of nicotine or the excretion of cotinine may differ by race. Racial differences in cotinine levels may provide clues to the reasons for the observed lower cessation rates and higher rates of some smoking-related cancers in Blacks. (*Am J Public Health* 1990; 80:1053–1056.)

Introduction

Cotinine, a major metabolite of nicotine, is currently considered the best indicator of tobacco smoke exposure.[1] It is specific for nicotine, has a long half-life (15–40 hours), and its level is thought to be directly proportional to the quantity of absorbed nicotine.[2] The quantity of nicotine absorbed by smokers is quite variable, being dependent upon its concentration in the smoke, the individual's smoking pattern, and the smoke pH.[3] Less is known regarding characteristics which influence the circulating levels of nicotine and cotinine or their maintenance in body fluids.[4–6] Such information may assist in the study of nicotine addiction and illnesses attributable to the toxic effects of this drug.

This paper will assess the differences in cotinine levels in a biracial group of young adults who, as determined by self-report, are cigarette smokers. Possible behavioral and metabolic differences which might account for this observation are evaluated.

Methods

The Coronary Artery Risk Development in (Young) Adults Study (CARDIA) is a longitudinal study of the antecedents and risk factors for cardiovascular disease in a cohort of 5,115 Black and White men and women ages 18–30 years at their initial examination in 1985. The sample was recruited to achieve approximately balanced subgroups of self-reported race, gender, education (high school or less and more than high school) and age (18–24 and 25–30 years) in Birmingham, AL; Chicago, IL; Minneapolis, MN; and Oakland, CA. Data were collected on a variety of risk factors as previously described.[7]

This report focuses on subjects who reported, on an interviewer-administered questionnaire, current, regular cigarette smoking of at least five cigarettes per week almost every week for at least three months. Smokers were queried regarding the frequency of inhalation, the number of cigarettes smoked daily, the total number of years of regular smoking, and current as well as past brand choices including questions about cigarette length, flavor, and filter. Information was also collected on cigar, pipe, smokeless tobacco, and nicotine gum use as well as weekly exposure to sidestream smoke.

The amount of tar, nicotine, and carbon monoxide in the cigarette brands was estimated from the Federal Trade Commission (FTC) Report on January 1985.[8] A crude measure of daily nicotine exposure was estimated as the reported number of cigarettes smoked per day × the nicotine content of the reported cigarette brand.

Blood was collected under a standardized protocol. A 1 ml aliquot of serum was frozen and shipped to the Clinical Biochemistry Laboratories at the American Health Foundation. Cotinine was determined by radioimmunoassay using the method of Haley, *et al*,[9] after a modification of the method described by Langone.[10]

A 3.4 percent sample of randomly selected blind duplicates was submitted by the field centers over the entire study period for an external assessment of quality. Cross-classification of the duplicate samples of both smokers and nonsmokers over five categories of cotinine levels (0–13 ng/ml, 14–99, 100–249, 250–499, ≥ 500) yielded a 91 percent (177/194) exact agreement rate. The agreement declined as the cotinine levels increased. Internal quality control was maintained as well; the interassay coefficient of variation was 7 percent.

Thiocyanate (SCN) was also quantitated by the laboratory according to the automated procedure described by Butts, *et al*.[11] SCN is a metabolite of hydrogen cyanide, a toxic gas present in tobacco smoke. It also occurs naturally in certain foods, making it a less specific marker of cigarette

smoking.[9] The decision to analyze SCN on a subset of samples was made after the start of the examination. Thus, SCN analyses were performed on samples left from the cotinine assays. Although the laboratory selected the subset, their selection criteria were based on the sample cotinine level and not the demographic characteristics of the subjects. SCN was measured on approximately 75 percent of the smokers.

Confidence intervals and statistical tests for the cotinine values are based on the Wilcoxon rank sum procedure. Similarly, Spearman nonparametric correlations were calculated for cotinine and other variables. Correlation coefficients were compared using the Fisher's Z transformation.[12]

A number of linear models were examined to assess the contribution of each of the independent variables to the cotinine measurement. We have chosen to present the multiple linear regression model of the untransformed cotinine because of its simplicity and because the variance of cotinine was reasonably stable over all levels of nicotine exposure. Other models, including log cotinine as the dependent variable, produced similar results. Separate analyses were performed for each of the four geographic areas as a check of the consistency of the major findings. All analyses were performed using the Statistical Analysis System (SAS).[13]

Results

Current cigarette smoking was reported by 1,545 (30 percent) of the 5,115 subjects; characteristics of these smokers have been described previously.[14] One-hundred-twenty-one participants were excluded from analyses (18 were missing the serum cotinine measure, 68 had uncodable cigarette brands, and 35 were regular users of cigars, pipes, smokeless tobacco, or nicotine gum). This left 1,424 (92 percent) smokers available for analyses.

Self-report appeared to be a satisfactory indicator of cigarette smoking when compared to serum cotinine levels. Overall, 95.0 percent of subjects who reported current smoking had cotinine levels > 13 ng/ml[15] (positive predictive value, PPV) while only 5.4 percent of the reported 3,508 non-smokers had cotinine levels above this cutpoint (false negative rate). PPV and false negative rates were slightly lower in Whites than Blacks (PPV: 92.9 percent vs 96.6 percent; false negative rates: 4.5 percent vs 6.5 percent).

Cotinine levels were higher in Black smokers than in White smokers; however, the estimated daily nicotine exposure and thiocyanate levels were higher in Whites than Blacks (Table 1). Black subjects smoked cigarettes of higher nicotine content and more frequently chose mentholated brands. White subjects smoked a greater number of cigarettes per day and reported more frequent inhalation than Black smokers. Fifty-five percent of Black smokers smoked one of two specific brands of cigarettes while only 10 percent of White smokers smoked these brands.

The highest correlation between cotinine and the other exposure measures (cigarettes smoked per day, daily nicotine exposure, thiocyanate, nicotine content of the cigarette) was found with the reported number of cigarettes smoked per day; the correlation coefficient was lower in Black smokers than White smokers (0.46 versus 0.64, $p < .0001$).

Cotinine levels were higher in Blacks in each category of the number of cigarettes smoked per day (significant for all but 21–40 cigarettes category, Figure 1), yet thiocyanate levels were not different between the races except for the upper category in which White smokers had greater levels (Figure 2). A racial comparison of cotinine and thiocyanate levels by daily nicotine exposure produced similar results.

Cotinine levels were 83.3 ng/ml higher in Black smokers than White smokers after adjusting for the number of cigarettes per day, nicotine content of the cigarette, years of smoking, inhalation frequency, weekly sidestream smoke exposure, age, education, and gender (Table 2). No two-way interaction terms yielded significant regression coefficients. Marijuana use and body mass index were also examined and although both yielded significant negative coefficients, only a modest reduction in the race coefficient was observed. The results of a similar regression on thiocyanate showed no association with race.

The race differential was explored further. In each of the four separate linear regression models representing the CARDIA centers, and including all the factors listed in Table 2, the

***calculated as nicotine (mg) × cigarettes per day.

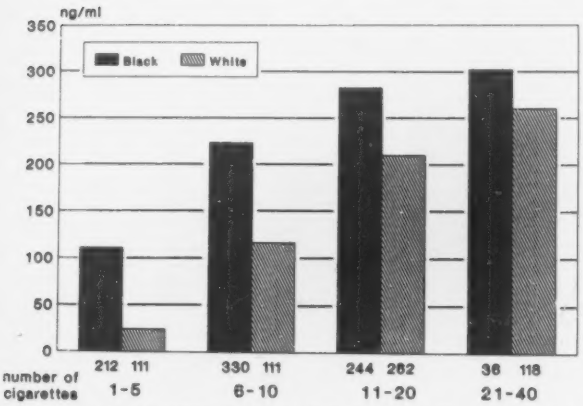

FIGURE 1—Median Cotinine (ng/ml) by Daily Number of Cigarettes Smoked
Numbers directly below bars are sample sizes. Racial comparisons within category of cigarettes smoked are significant ($p < .0001$), except for 21–40 cigarettes category ($p = .34$). Nine White subjects who reported smoking > 40 cigarettes per day were excluded.

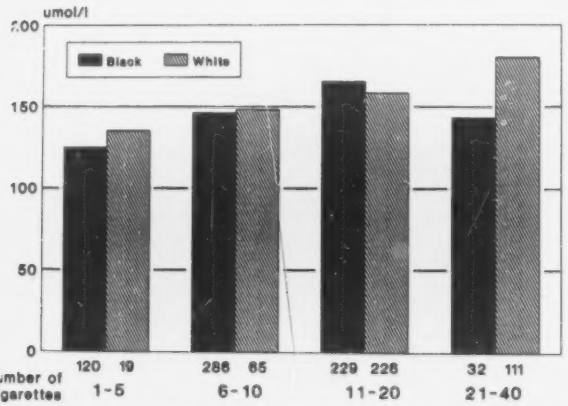

FIGURE 2—Median Thiocyanate (umol/l) by Daily Number of Cigarettes Smoked
Numbers directly below bars are sample sizes. Racial comparisons within category of cigarettes smoked are not significant except for 21–40 cigarettes category ($p < .001$). Nine White subjects who reported smoking > 40 cigarettes per day were excluded. Median thiocyanate is nearly identical to the mean; the median is presented for comparability to Figure 1.

race coefficient was found to be significant and consistent (Birmingham, 72.3; Chicago, 125.6; Minneapolis, 73.5; Oakland, 88.0; all $p < .0001$). The race coefficient was also significant in models representing smokers of mentholated (89.0, $p < .0001$) as well as non-mentholated cigarettes (51.5, $p = .0009$). Highly significant racial differences were also present in all three educational groups (< 12 years, 12 years, > 12 years) examined.

Discussion

In this cohort of smokers, race was strongly and consistently associated with serum cotinine even after adjustment for factors known to affect its concentration. To our knowledge, this finding has only been reported in one other study, as a chance finding[16]; misreport of exposure or metabolic differences were considered as an explanation of this finding in that study. As expected, we found that individual smoking patterns were also important factors in the prediction of cotinine levels in CARDIA smokers, with the quantity smoked most strongly correlated with cotinine in univariate and multivariate analyses.

There are several possible explanations for the higher cotinine levels in Black smokers. First, a reporting bias could account for the difference. A number of studies have shown that smokers tend to underreport their consumption of cigarettes.[17] However, a race differential in reporting appears unlikely (as was also shown in the National Health Interview Survey[18]). Our calculations indicate that all Black smokers would have to smoke nearly two times what they report to eliminate the race differential. Also, thiocyanate levels were equivalent between the races when the quantity smoked is taken into account (except in the 21–40 cigarettes category in which White smokers had higher thiocyanate levels). This also suggests that self-report is comparable between the races. Furthermore, underreporting might be expected to be different in various educational levels: however, we found the race differential in cotinine levels in all educational groups. The race differential in the false negative rate was also examined as a contributor to the cotinine differential. If, among Blacks, a large number of light smokers reported not smoking (false negatives), the average cotinine level reported here for Blacks may be inflated. However, upon examination of all participants considered "smokers" by their cotinine level, similar racial differences in the average cotinine level were observed. None of these findings supports a reporting bias as an explanation for the race differential in cotinine levels.

There are a number of factors in the style of smoking such as depth and frequency of inhalation, unsmoked butt length, and obstruction of filter ventilation which affect exposure.[17] Inhalation differences between the races in CARDIA favored higher nicotine exposure in the White smokers; this was not observed in the cotinine results. The amount of the cigarette which was smoked and the degree of filter obstruction were not ascertained from the CARDIA smokers. Possible differences in these factors could only partially account for higher cotinine levels in Black smokers.

We conclude that neither the number of cigarettes

smoked, the nicotine content of the cigarette, nor the frequency of inhalation can account for the observed racial difference in cotinine. It is possible that our adjustment for these or other unknown variables has been inappropriate. For example, since Blacks differed from Whites in the brands they smoked, a particular brand of cigarette may be the culprit. Mentholation might also account for differences. Mentholated cigarettes, smoked by 89 percent of Black smokers but only 30 percent of White smokers, might account for underreporting of inhalation frequency because of the anesthetic effect that menthol provides. A deeper and more frequent inhalation pattern in such smokers might result in a greater nicotine exposure and thus higher cotinine levels. However, cotinine levels, adjusted for the known covariates, were significantly higher in Blacks smoking non-mentholated cigarettes as well as in those smoking mentholated cigarettes. Mentholation does not appear to explain the race differential.

Finally, differences may exist in nicotine absorption or nicotine metabolism between the races. Tolerance to nicotine has been shown to be regulated by genetic factors in mice.[19] In man, ethnic differences are known to exist in the metabolism of drugs and other xenobiotics,[20] of which nicotine is an example. The finding of racial differences in cotinine levels across geographic areas and gender groups are consistent with a genetic mechanism.

Furthermore, the induction of microsomal enzymes might be varied across the two groups or differences in urine elimination[4] of nicotine or cotinine might account for the dissimilarity. Blacks could excrete less unmetabolized nicotine than Whites due to urine pH differences or metabolic induction. Additionally, diet could influence urine output and pH in one racial group. We were unable to address these possible explanations in this study.

The possible association of racial differences in cotinine levels to two public health issues should be addressed. The proposed associations are clearly speculative and suggest avenues for further research. First, cotinine, as an indicator of nicotine exposure, may be a reasonable indicator of nicotine dependence. Consequently, it is intriguing that cessation rates are higher in Whites and Blacks.[21] It is unclear whether Whites are more successful at cessation than Blacks because of a lesser nicotine dependency or other factors such as greater participation in cessation programs. The predictors of these success rates merit further investigation.

Second, higher average cotinine levels in Black smokers correspond with their higher incidence of several tobacco related cancers, particularly among young men.[22] Certainly the overall greater proportion of smokers among Blacks than Whites account for some of this differential, but perhaps not all. The biologic plausibility of such an association remains unclear. Although cocarcinogenic activity has been found for nicotine,[23] it has not been shown for metabolites of nicotine, including cotinine.[24]

In conclusion, considerably higher cotinine levels were observed in Black than in White smokers and this was not explained by reporting bias or nicotine intake differences. The difference in cotinine levels may be due to innate differences between the races in the metabolism or excretion of nicotine or cotinine. The findings may be relevant to understanding racial differences in the risk of nicotine addiction and tobacco-related cancers.

Apparent Underreporting of Cigarette Consumption among Mexican American Smokers

ELISEO J. PÉREZ-STABLE, MD, BARBARA VANOSS MARÍN, PHD, GERARDO MARÍN, PHD, DEBRA J. BRODY, MPH, AND NEAL L. BENOWITZ, MD

Abstract: To determine the accuracy of self-report of cigarette consumption among Mexican American smokers, we compared self-reported cigarette use and serum cotinine concentrations in a sample of 547 participants in the Hispanic Health and Nutrition Examination Survey (HHANES). We defined underreporting of cigarette use as a cotinine to cigarette-per-day ratio of > 0.142 μM/l which represented a substantial discrepancy between self-reported consumption and serum cotinine. Of the 98 men and 97 women who reported smoking one to nine cigarettes/day, 20.4 percent and 24.7 percent, respectively, underreported their cigarette consumption. Underreporting was less common among men and women smoking 10 to 19 cigarettes/day (8.3 percent and 10.8 percent, respectively) and 20 or more cigarettes/day (2.2 percent and 2.9 percent, respectively). Comparison of underreporters to other smokers by demographic characteristics within sex and cigarettes/day categories showed no differences. Differences in cotinine metabolism and extremely efficient smoking are alternative explanations that can not be ruled out with these data. We believe, however, that a proportion of Mexican American light smokers may underreport the quantity of cigarettes smoked per day, and may truly be moderate or heavy smokers. (*Am J Public Health* 1990; 80:1057–1061.)

Introduction

Over the past three decades, epidemiological surveys have relied on self-reported smoking behavior to determine current smoking prevalence, and to quantify tobacco consumption in cigarettes per day.[1–3] Because of possible deception in reporting smoking status, biochemical tests to validate self-reported cessation from cigarette smoking have become necessary measures in evaluating programs to help smokers quit.[4] Studies evaluating the relation between biochemical measurements and self-reported cigarette consumption among known smokers indicate that serum levels of nicotine and of its principal metabolite cotinine plateau above 20 cigarettes per day.[5,6] Behavioral factors related to the way a cigarette is smoked may be more important in maintaining a smoker's nicotine level than the actual nicotine delivery of a given cigarette brand as determined by a cigarette smoking machine and reported by the Federal Trade Commission.[7]

Regional and national surveys have consistently shown that Mexican Americans differ in their smoking behavior when compared to Whites who are not Hispanic.[8–13] Men of both groups smoke in similar proportions and smoking rates are higher among White women, but Mexican American smokers report an average of 10 to 12 cigarettes per day compared to 19 to 23 for Whites and 14 to 15 cigarettes per day for Blacks.[13,14] Because the proportion of light smokers among Mexican Americans is substantially greater than among Whites, we hypothesized that underreporting may partly account for this difference.

To compare self-reported cigarette use with a biological marker of smoking behavior, we evaluated the serum cotinine levels in 547 Mexican American smokers who participated in the Hispanic Health and Nutrition Examination Survey (HHANES) in the Southwestern states.

Methods

Southwestern HHANES

The Mexican American portion of HHANES was conducted in the Southwestern states of Arizona, California, Colorado, New Mexico and Texas between 1982–1983 by the National Center for Health Statistics (NCHS). A stratified probability sample of the civilian, noninstitutionalized Mexican American population living in these states was generated using a four-stage process.[15] HHANES included both a household interview and a medical examination, conducted in either Spanish or English. Data on smoking behavior and demographic information were collected. A total of 4,735 Mexican Americans age 20 to 74 years were selected for the survey, with 3,324 (70.2 percent) completing the physical examination portion where blood was drawn. Details of the sample design, operational plan, and quality control procedures are described elsewhere.[15]

The Cotinine Sample

The study population in this report is a subsample of the examined HHANES Mexican American population. Eligibility was based on current smoking status and the availability of 0.5 ml of frozen serum in 1986. Stratifying by sex (male/female) and the number of self-reported cigarettes smoked (1 to 9, 10 to 19, ≥ 20), persons were randomly selected from those with available serum in order to have 90 to 98 subjects per cell. Due to the limited number of women smoking 20 or more cigarettes per day, only 70 persons could be selected for that cell. Table 1 shows the distribution of the cotinine sample in the six cells with the corresponding total number of examined Mexican American HHANES smokers in each cell. The proportion of persons by cell selected from the total sample ranged from 44 percent to 80 percent.

Cotinine Analysis

Measurement of the concentration of cotinine in the serum of persons who reported smoking more than five cigarettes per day was performed using automated capillary gas chromatographic techniques described in detail in other publications.[16,17] Cotinine, principal metabolite of nicotine,

has a half-life averaging 19 hours, compared to a half-life of two hours for nicotine.[18,19] There are no data on possible ethnic or racial differences in the metabolism of nicotine among habitual smokers.

Excess serum on HHANES participants was stored at the Centers for Disease Control laboratory at a temperature of minus 70 degrees Celsius. Samples were shipped to San Francisco for cotinine assessment on dry ice and thawed prior to analysis. Cotinine analyses were completed within five years of serum collection, and concentrations of cotinine in frozen serum have been found to be stable over at least a five-year period (unpublished data, N.L. Benowitz). Serum cotinine concentration from smokers reporting one to five cigarettes per day was assayed by the same capillary column gas chromatography method, but modified with a sample concentration step to increase sensitivity. Standards of 0.001 (0.2), 0.003 (0.5), 0.006 (1.0), 0.028 (5.0), and 0.057 μM/l (10 ng/ml) were used. The limit of detection was about 0.001 μM/l (0.2 ng/ml). Results from these two methods for measuring cotinine on the same sample are identical.

Based on data from studies[20] conducted with heavy smokers (average of 36 cigarettes per day) who were restricted to 15, 10, and 5 cigarettes per day, a maximum serum cotinine level of 0.142 μM/l (25 ng/ml) per cigarette smoked was achieved by these extremely efficient smokers. This corresponds to an intake of nicotine of approximately 3 mg per cigarette. Thus, we have defined underreporting of self-reported cigarette consumption as a serum cotinine per cigarette value exceeding 0.142 μM/l (25 ng/ml) per cigarette. In support of this cutoff are the data of Shiffman, *et al*,[21] who measured cotinine levels in smokers who habitually smoke no more than five cigarettes per day. The average cotinine level per cigarette smoked was 0.08 μM/l (SD = 0.067) (14.0 ng/ml; SD = 11.8), which is nearly identical to the 0.07 μM/l (SD = 0.031) (12.5 ng/ml; (SD = 5.4) value for more dependent smokers reported by Benowitz and colleagues.[19]

Data Analysis

Data were analyzed using SPSSX.[22] Comparisons of proportions were made with chi squares and means were compared by t test and analysis of variance. An acculturation scale modified from Cuellar and colleagues[23] was used to divide the population into low, middle, and high tertiles for the purpose of these analyses. The poverty threshold defined in 1982 dollars by the Bureau of the Census was used to categorize the sample by income.[24]

Results

The demographic characteristics of the 547 Mexican American smokers are shown in Table 1 stratified by sex and self-reported cigarettes per day. This sample of smokers is not representative of Mexican Americans in the Southwest US because of the criteria used for selection. Light smokers (1–9 cigarettes/day) were younger than moderate (10–19 cigarettes/day) and heavy smokers (≥ 20 cigarettes per day). Acculturation scores were lower among men compared to women for each category of smokers and among light smokers compared to moderate and heavy smokers. Distribution by years of education completed, income below or above the poverty level, and the time blood was drawn were similar by sex and category of smokers.

Data from smokers who underreported cigarette consumption, as defined by a cotinine per cigarette ratio exceeding 0.142 μM/l (25 ng/ml) per reported cigarette, as shown in Table 2. Of the 98 men and 97 women light smokers, 20 (20.4 percent) and 24 (24.7 percent), respectively, exceeded 0.142 μM/l per cigarette with a mean cotinine per cigarette almost twice the threshold. Mean cotinine levels for light smokers were 4.3 times greater for men and 4.9 times greater for women who underreported than among the other smokers. Among moderate smokers the proportion underreporting cigarette consumption decreased to 8.3 percent for men and 10.8 percent for women. Heavy smokers were the least likely to be classified as underreporters with only two men (2.2

percent) and two women (2.9 percent). Comparison of the demographic characteristics of the 66 smokers classified as underreporting cigarette consumption to the other smokers by smoker category and sex show no differences by any of the variables examined including acculturation score. None of the 66 smokers classified as underreporters used cigars, pipes, or smokeless tobacco.

Among the underreporting light and moderate smokers, 36 indicated that they smoked a greater number of cigarettes in the past than at the time of the survey. If this number is used as an alternative value for self-reported consumption, then the proportion of underreporters among self-reported light smokers would decrease to 6.1 percent for men and to 15.5 percent for women. A similar decrease in underreporters would occur among moderate smokers to 3.1 percent of men and 7.5 percent of women. None of the four underreporting heavy smokers reported smoking a greater number of cigarettes in the past than at the time of the survey.

In order to quantify the number of cigarettes underreported by these smokers, an average minimum increase in serum cotinine of 0.057 μM/l (10 ng/ml) per cigarette smokes was estimated to occur.[20] A range of underreported cigarettes per day was derived from the expected minimum increase (0.057 μM/l) and the expected maximum (0.142 μM/l) increase in serum cotinine. Among the men and women light smokers, we estimated that they were actually smoking from 3 to 14 and from 4 to 17 more cigarettes per day, respectively. Among moderate smokers the estimated range of additional cigarettes smoked per day was 3 to 25 for men and 4 to 26 for women.

The average serum cotinine of the Mexican American smokers in this sample are shown in Table 3 by sex and smoker category. The overall values for moderate and heavy smokers are somewhat lower than the average level of 1.47 μM/l (259 ng/ml) reported among 450 smokers of 10 or more cigarettes per day who were volunteers at the blood banks in Bergen County, New Jersey (ethnicity not stated, but presumably mostly Whites).[6] Pearson correlations between cotinine levels and self-reported cigarettes per day are weak for moderate and heavy smokers and stronger for light smokers. Analysis of variance showed that serum cotinine increases with number of cigarettes smoked per day ($F(2,545) = 104.7$, $p < .0001$), age ($F(1,432) = 8.5$, $p = .004$), and acculturation level ($F(2,545) = 3.5$, $p = .03$) related. Sex, educational level, poverty status, and time blood was drawn did not have a consistent influence on cotinine concentration.

Discussion

The measurement of cotinine concentration in blood, urine, or saliva has been used predominantly to verify self-reported smoking status among persons claiming to have quit using cigarettes.[25–29] Use of cotinine measurements to evaluate underreporting in the quantity of self-reported cigarettes smoked per day has not been previously conducted. Applying this method to analysis of a sample of HHANES Mexican American smokers indicates that at least 20.4 percent of men and 24.7 percent of women who reported smoking less than 10 cigarettes per day may be underreporting their actual consumption.

We initiated this research to validate biochemically the finding in the Southwest HHANES (and other surveys) that Mexican Americans are mostly light or moderate smokers. Our findings support an overall lower level of dependence on nicotine as compared to another large community sample of non-Hispanic smokers.[6] However, a subset of those Mexican American smokers who report less than 10 cigarettes per day are more dependent on nicotine than the self-reported number of cigarettes would indicate. If a substantially greater proportion of Mexican American smokers are moderate or heavy smokers, then the related health risks for cardiovascular disease and cancer are greater than that determined by self-report. This could also have implications for planning and conducting smoking cessation interventions among Mexican Americans. The need to intensify ongoing community interventions based on culturally appropriate self-help methods[30] or to complement this with individualized or physician-mediated interventions must be considered since many Mexican Americans may not be light smokers.

The proportion of underreporting among light and moderate smokers was reduced by more than half when the maximum number of cigarettes smoked in the past was used in place of the self-reported number at the time of the survey. This may reflect the desire among many smokers to smoke less and the accurate reporting of past history may actually represent current habits. Regardless, the maximum number of cigarettes smoked per day in the past may be an important additional measure of self-reported smoking behavior among Mexican Americans.

Coultas and colleagues recently found discrepancies between self-reported and validated cigarette smoking in a community survey of New Mexico Hispanics.[31] Their study found that among former smokers older than 18 years of age, the proportion with a salivary cotinine greater than 0.11 μM/l (20 ng/ml) (defined as current smoker) was as high as 21.4 percent. Our study expands on these findings in that we are estimating a similar rate of apparent underreporting in self-reported number of cigarettes consumed among Mexican American light smokers. The substantial level of inconsistencies between the number of self-reported cigarettes smoked and the results of cotinine concentrations may also reflect a tendency among Latinos to give socially desirable responses.[32]

The use of a cotinine per cigarette ratio exceeding 0.142 μM/l (25 ng/ml) as the cutoff to define underreporting is conservative. In another study, nine heavy smokers (average 36 cigarettes per day) were restricted to five cigarettes per day and only two were able to achieve cotinine to cigarette ratios exceeding 0.142 μM/l per cigarette.[19] In contrast, people who are carefully documented as smoking five or fewer cigarettes per day have intakes of nicotine and levels of cotinine per cigarette similar to heavy smokers during unrestricted smoking.[20] Considering these data, we conclude that in setting the criterion at 0.142 μM/l per cigarette we are probably underestimating the prevalence of possible underreporting.

It is possible that some underreporters in HHANES were extraordinarily efficient in smoking cigarettes, but this is unlikely to fully explain our results given that heavy smokers with restricted access to cigarettes were unable to achieve comparable cotinine levels. Another possible alternative explanation for our findings involves ethnic or racial differences in the metabolism of nicotine and clearance of cotinine. Wagenknecht and colleagues[33] have proposed that higher serum cotinine levels among Black compared to White smokers (despite fewer self-reported cigarettes consumed per day) were due to racial differences in the metabolism of nicotine and not to a reporting bias. If Mexican Americans metabolize nicotine more slowly, our results would be partly accounted for without underreporting. Alternatively, light and moderate smokers for any ethnic group may have a much slower metabolism of nicotine or a slower clearance of cotinine than the average habitual smoker.

Several limitations in this study need to be considered. Although HHANES results are generalizable to Mexican Americans in the Southwestern states, our study selected smokers based on availability of frozen serum and may not apply to all smokers. Given that 42 percent of HHANES Mexican American smokers reported smoking less than 10 cigarettes per day, the highest estimates of underreporting apply to a substantial proportion of this population. However, it is possible that if smokers had been informed that a biochemical validation test would be conducted, underreporting would be less frequent. The HHANES Puerto Rican and Cuban American samples were not evaluated in this study, but the proportion of light smokers in those Latino subgroups is less than among Mexican Americans, and thus underreporting may be less common. Finally, our observations in Mexican Americans may be a phenomenon of all light cigarette smokers' self-reporting on quantity independent of ethnicity. In fact, Warner[34] has suggested that survey reports of cigarette consumption underestimate consumption estimates based on production and sales. A more recent comparison concluded that there was no apparent increase in underreporting cigarette smoking in surveys since 1975.[35] The magnitude of underreporting is greater among light smokers, and thus studies using cotinine measurements and applying the method described in this paper may be more important in these populations.

ACKNOWLEDGMENTS

We acknowledge the assistance of Peyton Jacob and Lisa Yu in conducting laboratory analyses, Raymond J. Gamba for invaluable help in data management, and Sylvia Correro and Lesley Grizzell for administrative support. Robert Murphy, Suzanne Haynes, Claire Harvey, and the staff at the National Center for Health Statistics made this study possible. Peter Gergen, Cliff Johnson, Steven Cummings, Steve McPhee, and Thomas Coates made helpful suggestions on earlier drafts. NIH Consensus Development Conference Announced on Hyperparathyroidism

Hyperparathyroidism is increasingly being recognized in asymptomatic patients, as a result of widespread use of multiphasic screening tests that lead to detection of hypercalcemia. Physicians are often uncertain about the diagnosis and management of patients with subtle or absent signs and symptoms but with a clear biochemical diagnosis of hyperparathyroidism. Especially difficult are decisions about indications for surgery and how patients should be monitored to detect silent organ damage, particularly progressive bone loss.

Because of these issues, the National Institute of Diabetes and Digestive and Kidney Diseases and the Office of Medical Applications of Research at the National Institutes of Health will co-sponsor a consensus development conference on Diagnosis and Management of Asymptomatic Primary Hyperparathyroidism. The meeting will be held October 29–31 at NIH, Masur Auditorium, in Bethesda, MD.

To register for this conference or to obtain further details, contact: Conference Registrar, Prospect Associates, Suite 500, 1801 Rockville Pike, Rockville, MD 20852. Tel: (301) 468-MEET.

Demographic Characteristics, Risk Behaviors, and HIV Seroprevalence among Intravenous Drug Users by Site of Contact: Results from a Community-wide HIV Surveillance Project

JANE MCCUSKER, MD, DRPH, BERYL KOBLIN, PHD, BENJAMIN F. LEWIS, EDD, AND JOHN SULLIVAN, MD

Abstract: We investigated differences in behaviors important for human immunodeficiency virus (HIV) transmission and HIV antibody status among 927 recent needle users enrolled in a multi-site HIV surveillance project in Worcester, Massachusetts. Subjects were enrolled at drug abuse treatment centers, other clinical sites, and a men's jail. Subjects at drug treatment centers reported less risky injection practices unexplained by demographic variables. Risky sexual practices were in general reported more frequently by men at the jail than men at other sites. However, HIV status showed little relation to enrollment site. These results have implications both for targeting of acquired immunodeficiency syndrome (AIDS) prevention programs to needle users not in drug abuse treatment and for potential selection bias in studies of intravenous drug users. (*Am J Public Health* 1990; 80:1062–1067.)

Introduction

Intravenous drug users (IVDUs) who share injecting equipment play an important role in the transmission of the human immunodeficiency virus type 1 (HIV-1), the causative agent of the acquired immunodeficiency syndrome (AIDS).[1] There is some evidence that IVDUs are not a homogeneous group, and that sub-populations exist with different risks of infection with HIV. Watters and Cheng described two sub-populations of IVDUs in San Francisco: the first was in somewhat regular contact with drug abuse treatment programs, while the second, contacted on the street and in jail, did not interact routinely with drug treatment.[2] Distinction between sub-populations of IVDUs is important both for program planners who may need to target programs differently for different sub-populations, as well as for epidemiologists and other researchers who need to understand the types of selection bias introduced by studying a particular sub-population.

HIV infection is a function both of risky behavior and of the probability that persons with whom the behavior is practiced are infected. Seroprevalence differences may not reflect differences in risky behavior in areas where HIV has been introduced relatively recently. This report investigates differences in risky behaviors and HIV seroprevalence in IVDUs enrolled at multiple sites in a community-wide AIDS prevention program. The data were collected as part of a surveillance system which monitors HIV infection and related behaviors among IVDUs and their sexual contacts in Worcester, Massachusetts.[3] Worcester has an IVDU population estimated in 1988 at about 4,000 and from 1983–86 was the site of a significant epidemic of delta hepatitis.[4] Since 1987, public health interventions targeted at IVDUs which build upon and are coordinated with the ongoing hepatitis B prevention program have been collaboratively planned by members of the Worcester AIDS Consortium, including the city health department, drug abuse treatment facilities, correctional facilities, community health centers, and support and advocacy programs for persons with HIV infection.

Methods

Study enrollment began at the men's county jail in September 1987, followed by the city health department's hepatitis B and HIV clinic and one community health center in December 1987, the three drug abuse treatment centers in February 1988, and the second community health center and a clinic for sexually transmitted diseases run by the State Department of Public Health in April 1988. Interviews completed by the end of December 1988 are included in this study.

Interviews with a short, standardized encounter form are conducted by project staff who are not involved in the care or treatment of the individual. At the three drug abuse treatment centers (a therapeutic community, an inpatient 21-day methadone detoxification facility, and an outpatient clinic providing methadone services and drug-free counseling), the encounter form is administered routinely at admission. At one of the community health centers it is administered routinely to all high-risk clients who are referred for HIV counseling. At those sites where use of the encounter form is part of the client's record, consent is obtained for release of encounter form data to the study. At all other sites, consent is obtained prior to administration of the encounter form. At the men's jail an AIDS educational session, at which attendance is voluntary, is given once a week by a team from the City Department of Public Health.* At the end of the session, the inmates are informed about the study and asked to participate.

Information collected in the encounter interview includes sociodemographic variables, drug use and social behaviors, and results of previous HIV antibody testing (see appendix). Subjects are asked about relevant behavior during their lifetime and during the most recent period of at least one week and not more than three months of "free living," when not in any institutional setting. The main drug use and sexual behaviors reported in this paper are those reported for this "risk period" and are referred to subsequently as "recent" behaviors.

At all sites, voluntary HIV antibody testing in conjunction with pre-test counseling is available following the interview. Initial serological screening is carried out using Food and Drug Administration (FDA)-approved commercial ELISA (enzyme-linked immunosorbent assay) kits. Each sample which tests positive by the ELISA is confirmed using a Western blot test.**[7]

In this report we use only data from the first contact of each individual with the Worcester program. Cross tabulations, stratified by sex, were used to assess between-site differences in demographic variables, drug and sexual behaviors, and HIV status.

In order to assess site-specific differences controlling for demographic variables, logistic regression modeling[6] was performed on HIV antibody status and four recent behaviors: sharing of injection equipment; use of bleach to clean injection equipment by those who reported sharing; sexual contact with two or more partners (for females, male partners only were considered); and use of condoms during sex among those with two or more sexual partners. All behaviors were dichotomized (yes or no).

Interpretation of the current HIV antibody test results is complicated by the tendency for those who had previously been tested not to be retested, particularly if they had a positive test result. Therefore, we chose to use the cumulative test results of those ever tested, derived from the results of testing in the Worcester program, and self-reported results of previous HIV antibody tests for individuals not tested in the Worcester program. Separate regression models were run for males and females. Goodness of fit of the logistic models was assessed using the Hosmer-Lemeshow statistic.[6]

Results

Participation rates were as follows: about 50 percent of those attending the educational sessions at the jail; about 85 percent of clinic patients referred for counseling; and over 90 percent of those admitted to the drug treatment centers. The participation rate at the jail is an underestimate, as many prisoners were observed to attend two or more of the sessions before deciding to participate. In the period ending December 31, 1988, 2,174 individuals had been enrolled in the project, 927 (43 percent) of whom reported recent ("risk period") needle use.

Characteristics of recent needle users by site of initial study enrollment are shown in Table 1 (males) and Table 2 (females). On transsexual individua! has been omitted from analysis. Clinic sites have been grouped: most were enrolled at health department clinics.

Significant differences between the enrollment sites were found for almost all demographic variables, both among males and females. Among males, the youngest needle users were enrolled at the jail. In both sexes the oldest needle users and those who had been injecting for the longest time were enrolled at the outpatient drug treatment center. The drug abuse treatment centers attracted lower proportions of racial and ethnic minority members, and higher proportions of high school graduates. Those enrolled in the residential drug abuse treatment centers were more often resident outside Worcester than those at the outpatient sites.

Drug use behaviors also differed significantly by site of enrollment. Needle users entering drug abuse treatment reported the highest frequency of injection but the lowest proportion of sharing and sharers were more likely to have used bleach recently to disinfect their injection equipment. Among males, several other risky drug behaviors were also reported less frequently at drug treatment centers: visiting a "shooting gallery" and sharing injection equipment in New York City.

Less marked differences were found in sexual behavior by enrollment site. Among males, as the percentage reporting homosexual partners were very low, these have been combined with heterosexual partners for these analyses. Men at the jail were more likely to report multiple sex partners during the "risk period," and those with multiple partners were less likely to have used condoms.

Overall, 60 percent of males and 37 percent of females were tested for HIV antibody in the program, with lower percentages tested at the drug treatment centers. An additional 20 percent of males and 33 percent of females had been tested prior to enrollment in the Worcester program. The cumulative percentage ever reporting a positive test result was slightly lower at the inpatient and residential drug abuse treatment sites than at the other sites.

Logistic regression modeling controlling for demographic variables indicated that the odds of not sharing injection equipment were higher at all drug abuse treatment sites in comparison with the clinics (Table 3). In comparison with men at the jail, men at all three drug abuse treatment sites were less likely to share and confidence intervals (now shown) excluded unity. In both sexes, bleach use among needle sharers was higher in all drug abuse treatment center groups than the clinic group.

Sexual behaviors in the drug treatment groups differed from those at the clinics but the confidence intervals included unity (Table 3). However, men at the jail were more likely than men entering drug abuse treatment to report two or more sexual partners; among men with multiple partners, those at the detoxification center were more likely to use condoms than men at the jail and these confidence intervals (not shown) excluded unity.

In contrast with the between-site differences in drug and sexual behaviors, cumulative HIV status differed relatively little by enrollment site (Table 3). In an effort to explain the lack of congruence between the serological data and the risk behaviors, we investigated whether there were differences in risk behaviors between those ever and never tested at the drug abuse treatment sites (at the other sites too few had never been tested). We also examined the relation between risk behaviors and serological status among those who had been tested, stratifying by site of enrollment. No significant associations or consistent trends were found, although small numbers of seropositives at some sites limited the power of these analyses.

Discussion

We found significant differences by enrollment site in demographic characteristics and drug use behaviors of recent needle users. Needle users entering drug abuse treatment tend to be of higher socioeconomic status, and include fewer racial-ethnic minority members than those at other sites. Among the drug abuse treatment facilities, those offering

residential and inpatient services attract more young, unmarried clients from outside Worcester than the outpatient clinic. Clients entering outpatient drug abuse treatment are older and have longer injection histories than those entering residential drug abuse treatment, in part because most receive methadone services which require the client to have used heroin for at least one year prior to entry into treatment.

Our results suggest that needle users entering treatment have significantly lower levels of risky drug behaviors, including sharing of injection equipment and not using bleach for disinfection, than those at other sites. In spite of more frequent needle use among those entering drug abuse treatment, safer practices appear to be followed.

Among men, those at the jail report multiple sexual partners more frequently than those at the drug abuse treatment centers, and are less likely to use condoms than those at two of the drug treatment sites. In spite of these behavioral differences, there is little difference in HIV status, but testing was not universal.

We were not able to explain the lack of congruence between the serological data and the risk behaviors. Selection bias (selective testing at the drug abuse treatment sites of those with more risky behaviors) did not explain this finding. It seems more likely that the explanation lies in the cross-sectional study design and the use of prevalent rather than incident infection. For many study subjects, HIV infection may have occurred prior to the recent "risk period" for which risk behaviors were measured. For example, in a study of homosexually active males reported by our group, both prior and recent frequently of risky behavior were independently associated with HIV seroprevalence.[7] We were not able to carry out similar analyses on the present study population, as data were not collected on previous risk behaviors.

A second possibility is that previous HIV antibody testing may have affected recent risk behavior. Again, without information on previous behaviors, we were not able to assess this hypothesis.

A third possibility is that needle users who enter treatment represent a sub-population which is particularly motivated to reduce their risk of AIDS. Although they report a high frequency of needle use, they may have modified risk behaviors prior to entering treatment.

Reports having highlighted the significance of the recent epidemic of "crack" cocaine use for HIV transmission, in which sexual practices rather than IV drug use appear to be responsible for HIV transmission.[1] In March 1989, we began to collect information on "crack" use; about one-fifth of recent needle users have smoked "crack" although we have no information on frequency. Drug use rather than sexual behaviors appear to be associated with HIV seroprevalence in this study population, although these behaviors tend to be associated (unpublished data).

Demographic and behavioral differences in sub-populations of needle users have been reported by other researchers, although none have information on drug use and sexual behaviors from as many different enrollment sites as were possible in this study. Several studies from the United Kingdom have found that drug users in treatment were older, had used drugs for longer, and showed greater reductions in risk behavior.[8–11,***] Results of studies from different parts of the US, however, show inconsistent differences by site of enrollment.[2,12†,††,†††]

Several limitations of this research should be considered, including selection and measurement biases. Although the multi-site enrollment in this study allows some examination of possible selection bias, it does not eliminate such bias. Of particular concern is selection bias at the non-drug clinics and at the jail; at these sites, the HIV antibody testing may have attracted many of the participants and others have found that higher risk needle users tend to self-select for HIV testing in prisons.‡,‡‡

Measurement bias was avoided to some extent by having the interviews done by staff who were not involved in the individual's care or treatment. Nevertheless, study participants may have misrepresented their drug behaviors in efforts to impress the staff, or to obtain higher doses of methadone at drug abuse treatment sites. Factors such as social desirability and prior drug use by the interviewer can affect validity.[13,14] Self-reports of drug use may differ from "official" records, such as addict registers or hospital charts.[15–17] Self-reports of sexual behavior are of undetermined reliability and validity; this problem has been examined in homosexual males,[18] but has received little attention among IV drug users.

The demographic differences between needle users by enrollment site are cause for concern; Blacks and Hispanics who are at highest risk of HIV infection[19] are underrepresented in the sub-populations entering treatment.[20] Female needle users are also underrepresented at the inpatient and residential drug abuse treatment centers. Black women of

lower socioeconomic status are least likely to enter drug abuse treatment programs, and may only do so after exhausting informal resources.[21] Outpatient programs which offer child care are needed; methadone maintenance programs can be very effective, but may need to adopt a more lenient approach in order to keep clients in treatment.[22]

Our study has implications both for the conduct of AIDS prevention programs and for research. AIDS prevention programs need to target sub-populations of needle users with the most risky behaviors, particularly those not currently in treatment.‡‡‡ Incarcerated needle users are an important and very problematic group for prevention programs.[23,24]

Continued monitoring of IVDUs for HIV seroprevalence is important to identify high-risk sub-populations, to appropriately target prevention programs, and to evaluate the effectiveness of those programs. Samples of IVDUs entering drug treatment are often used for monitoring HIV exposure, partly because of their accessibility, and partly because the period before entering drug treatment is said to be characterized by a relatively high frequency of drug injection, and unsafe injection practices.[25] Although our results support higher frequency of drug injection in this sub-population, they do not support less safe injection practices. Use of data from drug abuse treatment programs for monitoring HIV exposure should not be adopted without further critical examination of the potential biases involved; data from drug users enrolled at different sites should not be pooled unless they have first been examined separately by site.

APPENDIX
Description of Study Variables

Demographics
- Age (years)
- Sex (male; female; transsexual)
- Race (Hispanic; black, non-Hispanic; white, non-Hispanic; Asian or Pacific islander; Indian/native American; other).
- Education: high school graduate or general education diploma (yes; no)
- Residence in city of Worcester (yes; no).

Prior experience
- Previously in jail (yes; no).
- Previously in drug abuse treatment, inpatient or outpatient (yes; no).

Drug use history
- Ever injected drugs, intravenously or subcutaneously (yes; no).
- Ever injected heroin (yes; no).
- Ever injected cocaine (yes; no).
- Injected drugs during the "risk period" (yes; no).

Drug use during "risk period"
- Frequency of injection (more than once/day; once/day; 3–6 times/week; 1–2 times/week; 1–3 times/month; less than once/month).
- Frequency of sharing needles, i.e., injecting with needles someone else has already used (once/day; 3–6 times a week; 1–2 times/week; 1–3 times/month; less than once/month).
- If sharing reported, was bleach ever used to disinfect "works" (yes; no).
- Sharing in a shooting gallery, i.e., a place where you pay with money or drugs to get in or to get high (yes; no).
- Sharing needles in New York City (yes; no).

Sexual behavior during "risk period"
- Number of female sexual partners (none; one; 2–9, 10–19; 20–49; 50 or more).
- Number of male sexual partners (none; one; 2–9; 10–19; 20–49; 50 or more).
- Sexual contact with someone you knew to have used needles since 1981 (yes; no).
- Received money or drugs in exchange for sex (yes; no).
- Sexual contact with a prostitute, i.e., someone who gets paid for sex with money or drugs (yes; no).
- Ever used condom during sex (yes; no).

HIV antibody testing
- Ever tested for HIV antibody, including current testing (yes; no).
- If ever tested, result (positive; negative; equivocal; unknown).
- Currently tested for HIV antibody, i.e., within one day of encounter interview at non-drug treatment sites, within 30 days of interview at the detoxification and the outpatient drug treatment facility, and within 45 days of interview at the residential drug treatment facility (yes; no). If currently tested, result (positive; negative; equivocal; unknown).

Joint US–Canadian Conference to Focus on Diabetes among Native Indians

"What Makes a Model Community Diabetes Program for American Indians Successful?" That will be the theme of a joint US—Canadian conference titled Diabetes and Native Peoples: International Issues in Education, Treatment, and Prevention, to be held November 7–9, in Minneapolis, MN. Sponsors include the Native American Research and Training Center (NARTC), Indian Health Service, Medical Services Branch—Health and Welfare Canada, American Diabetes Association, and the Canadian Diabetes Association.

This international conference will feature speakers from reservation communities and hospitals throughout Canada and the US, and will address common problems in establishing effective programs and providing care to Indian peoples with diabetes. Conferees will discuss development and implementation of model community diabetes programs. Standards of care and of health education recommended for Native peoples with diabetes also will be reviewed and discussed at the conference.

Continuing Education credit will be offered for physicians, nurses, and pharmacists. A $50 registration fee is required and covers the cost of the banquet dinner, Pow-Wow, and continuing education units. For further information, write or call: (USA), Dr. Robert Young, NARTC, 1642 E. Heler St., Tucson, AZ 87519, (602) 621-5560. Death Resulting from Motor Vehicle Immersions: The Nature of the Injuries, Personal and Environmental Contributing Factors, and Potential Interventions

GAREN J. WINTEMUTE, MD, MPH, JESS F. KRAUS, MPH, PHD, STEPHEN P. TERET, JD, MPH, AND MONA A. WRIGHT, BS

Abstract: We present an epidemiologic characterization of deaths from motor vehicle immersions, based on 77 deaths in 63 motor vehicle immersions in Sacramento County, CA, during 1974–85. All persons were autopsied; all but one of the deaths were due to drowning. Average annual mortality rates per million person years were 12 for males, four for females, 30 for Hispanics, six for White non-Hispanics, Blacks and Asians. Seventy-one percent of drivers and 60 percent of passengers had a blood alcohol concentration ≥22 mmol/L.

Most cases (57 percent) had an Injury Severity Score of 1 (minor injury) or 0 (no injury). Alcohol use was associated with higher Injury Severity Scores. Road curvature of 20° or greater was far more common at crash sites than at matched control sites one mile away(OR = 6.57, 95% CI = 2.93, 14.71). Guard rail placement along highly curved sections of roadway may be an effective preventive measure. (*Am J Public Health* 1990; 80:1068–1070.)

Introduction

Each year there are approximately 350 deaths in the United States resulting from motor vehicle immersions (unpublished data, Fatal Accident Reporting System, 1988). High motor vehicle-related drowning rates have been noted previously in places with many inland waterways such as Florida and Louisiana.[1] In Sacramento County, California, site of a large river delta and the location of this study, autopsy-confirmed drownings from motor vehicle immersions are more common than drownings from boating incidents (unpublished data, The Sacramento Drowning Study, 1987). To our knowledge, the nature and epidemiology of these deaths have not been described.

This study therefore sought answers to the following questions. Are deaths due to motor vehicle immersion actually drownings, or are they due to biomechanical trauma resulting from the crash event itself? By convention all such deaths have been classified as motor vehicle deaths, rather than drownings, since the adoption of the fifth revision of the International List of Causes of Death in 1939. What are the personal and environmental contributing factors for these deaths? What countermeasures are available and likely to be effective?

Sacramento County had 783,381 residents in 1980. The southwestern portion of the county is a river delta. Roads in this area are generally built on levees, some 30 feet above river level. These roads are two lanes wide, with lane widths of 10–12 feet, and have narrow shoulders. The roads are level except for the short distances needed to mount a levee; curves are generally not banked. We observed that speeds of travel commonly exceed 55 mph on major levee roads. In other rural portions of the county, roads may be built next to irrigation canals or other waterways.

Methods

The study period was 1974–85. Cases were identified through a register maintained by the coroner's office, which lists both the anatomical and external causes of death. Cases were defined as persons, regardless of their cause of death at autopsy, who were motor vehicle occupants and who entered the water by means of a motor vehicle immersion. We reviewed coroner's and police reports and interviewed investigative personnel. We also reviewed coroner's records for all motor vehicle deaths occurring in the county for 1980–85, but found no additional cases.

All cases were autopsied. Causes of death were abstracted directly from the autopsy report. Analyses pertaining to blood alcohol concentration (BAC) were restricted to cases in which death occurred within six hours of immersion, and blood sampling occurred within 24 hours of death. These criteria avoid spuriously low values resulting from post mortem sampling after prolonged survival, and spuriously high values resulting from putrefaction.[2]

Traumatic injuries were scored for severity using the Abbreviated Injury Scale (AIS), which assigns to individual injuries a numerical score between 1 (mild) and 6 (unsurvivable).[3] Injury Severity Scores (ISS) were computed.[4] As used in this article, the term "head injury" includes injury to the external soft tissues of the head and face, such as lacerations and abrasions. In calculating Injury Severity Scores, however, these superficial head injuries were coded as "External" injuries as required by standard scoring procedures.

Following the case-control method developed by Wright and Robertson,[5] each crash site (defined as the point at which the vehicle left the roadway) was compared with a point one mile distant, on the same road except as noted below, in the direction from which the vehicle had come. When the path of travel could not be reconstructed with certainty because of an intersection within one mile of the crash site, preference was given first to arterial rather than tributary roads; when the choice involved two roads of the same type, preference was given to the road adjacent to the water. Eleven of 63 immersion events were excluded from this analysis (path of travel uncertain, three cases; vehicle traveled less than one mile prior to immersion, three cases; crash occurred on private or restricted roadway and the investigators could not gain access, two cases; other, three cases). We limited the

crash site—control site comparison to road curvature, determined by the middle ordinate method.[5] Curvature was measured at 100 foot intervals for 500 feet in either direction from the point at which the vehicle left the roadway. Gradient and banking, evaluated in Wright and Robertson's earlier work, were each present in only two of the sites we studied.

Using our case identification methods as a "gold standard" procedure for crash site identification, we calculated the sensitivity and specificity of various minimum-curvature criteria as screening tests for identifying known crash sites. Sensitivity was defined as the number of known crash sites identified divided by the total number of known crash sites. Specificity was derived in an analogous manner.

We also inventoried risk-reduction features at crash sites, such as warning signs and guard rails, to learn whether post-crash modifications had been made. We used each crash site as its own historical control, comparing the detailed written and pictorial description in the earlier police reports with our observations in 1987–88. This analysis was limited to the 34 cases for which detailed police reports were available.

Average annual mortality rates were calculated based on place of occurrence, using Sacramento County data from the 1980 US Census to approximate a mid-interval population. All denominators are age-, race-, and gender-specific as appropriate. Rates are rounded.

Confidence intervals were calculated by the exact binomial method using Confidence Interval Analysis software.[7] Other analyses were performed with PC-SAS.

Results

There were 78 deaths identified, but one was excluded as the coroner's record could not be located. The 77 remaining deaths resulted from 63 motor vehicle immersions, all single vehicle events, of which seven led to multiple fatalities. Twenty-five immersions also involved a total of 37 vehicle occupants who survived. (Further information on survivors was not available.)

A car was involved in 65 deaths, a truck in 11, and a motorcycle in one. Fifty persons were drivers, and 27 were passengers. Three deaths were specified as job-related. Seventy-five deaths were classified by the coroner as unintentional, one as suicidal, and one as of undetermined intent.

In all but one fatality, drowning was reported as the sole cause of death, or drowning and one or more traumatic injuries were listed as multiple causes of death. The cause of death for the remaining case was "craniocerebral trauma with possible drowning."

The average mortality rate was eight per million person years. Cases ranged in age from seven months to 73 years; 38 were age 15–34; 57 cases were male. Mortality rates were 12 for males and four for females, per million person years.

The mortality rate for Hispanics was five times those for White non-Hispanics, Blacks, and Asians (30 for Hispanics, six for the other groups, per million person years). Hispanics accounted for 36 percent of these deaths, but made up only 9 percent of the county's population in 1980. This difference was not due to a disproportionate number of nonresidents among Hispanic cases. Sixty-three percent of Hispanic cases, and of all cases, lived in the county. While immersions involving any Hispanic deaths were more likely than others to result in multiple fatalities (OR = 7.5, 95% CI = 1.6, 35.3), this difference did not fully explain the high Hispanic mortality rate. The fatal immersion event rate was also higher for Hispanics than for non-Hispanics (20 and six per million person years, respectively).

Forty deaths occurred on Saturday or Sunday, twice the number predicted by the hypothesis of equal occurrence throughout the week ($\chi^2 = 17.19$, df = 6, $p < .01$). There were no significant differences in incidence by time of day.

A blood alcohol concentration (BAC) was determined in 75 cases; the specified eligibility criteria were met in 56. Five cases were children under age 15, none of whom had a positive BAC. Among older persons, 74 percent of drivers and 73 percent of passengers had a positive blood alcohol concentration; 71 percent of drivers and 60 percent of passengers had a BAC ≥ 22 mmol/L.

Serious biomechanical trauma was unusual (Table 1). Most persons had an Injury Severity Score of 1 (minor injury) or 0 (no injury). Fifty-one cases sustained a head injury, but 26 of these were AIS 1 injuries. Alcohol use was associated with higher Injury Severity Scores. Among cases meeting the alcohol sampling criteria, 15 of 18 cases with a score ≥ 10 had a BAC ≥ 11 mmol/L, as opposed to 23 of 36 cases with an ISS of 0 or 1 (OR = 2.83, 95% CI 2.05, 3.89).

Post-event interventions were uncommon. Only four cases involved immersion times of 30 minutes or less. Three of these four people, and 11 of all 77 cases, were given emergency care after retrieval from the water. One person survived long enough to be admitted to a hospital.

There were large differences in road curvature between crash and control sites. Crash sites had a median curvature of 19° over 1000 feet; the median curvature for control sites was 8° (difference = 11°, approx 95% CI = 2°, 18°). The differences in mean curvature were greatest over the 500 feet approaching the point where the vehicle left the roadway (Figure 1). Crash sites were far more likely than control sites to involve a curvature of 20° or greater (OR = 6.57; 95% CI = 2.93, 14.71). Conversely, crash sites were less likely than control sites to have curvatures of less than 5° (OR = .42; 95% CI = .24, .73).

The sensitivity and specificity of several minimum curvature criteria for identifying crash sites varied inversely (Table 2). None of the criteria evaluated was highly sensitive, but it was possible to identify approximately 50 percent of crash sites with a specificity of 75 percent or greater.

There were four multiple-crash sites, each of which had two fatal motor vehicle immersions during the study period. Three of these sites had curvatures of greater than 30° (34°, 66°, 84°) over 1000 feet. The fourth had a curvature of 4° (less than its control) and no other explanatory features.

At two of 34 crash sites for which complete police reports were available, guard rails existed between the road and water at the time the crash occurred. Guard rails had been added to

TABLE 1—Incidence and Severity of Head and Other Injuries in 77 Motor Vehicle Immersion Deaths, Sacramento County, California 1974–85

Overall Injury Severity		Head Injury Severity

five other sites, and extended at one of the first two locations, by the time our field investigation was conducted.

Discussion

These deaths represent an unusual subset of motor vehicle-related deaths, in that traumatic injury was generally minor if present at all. Death, generally by drowning, appeared to result more directly from the hostile environment in which the crash occurred. This may be particularly true for those cases involving minor head injury; transient disorientation or loss of consciousness may well result in death given that immersion has occurred. From the pathophysiologic viewpoint, these deaths are more properly considered drownings. From the prevention standpoint, their current classification as motor vehicle deaths seems appropriate.

The mortality rate for Hispanics was approximately five times that for other groups. These rates were calculated based on place of occurrence, but the observed difference did not result from a high proportion of out-of-county residents among Hispanic fatalities. A number of other factors may be involved. First, fatal immersions involving Hispanic vehicle occupants were more likely than others to result in multiple deaths. Second, the high risk roadways are in agricultural areas of the county. Since Hispanics in the Sacramento area are heavily involved in agriculture, their higher fatal immersion rate may result from a higher exposure to these roadways than that of other groups. Differences in alcohol use and driving experience may also play a role. A controlled study will be necessary to evaluate these possibilities.

TABLE 2—Sensitivity and Specificity of Various Minimum Curvature Criteria for Identifying Sites of 52 Fatal Motor Vehicle Immersions Occurring in Sacramento County, California 1974–85

Minimum Curvature over 1,000 feet (degrees)	Sensitivity (95% CI)	Specificity (95% CI)

Alcohol was a major contributing factor. Seventy-four percent of drivers meeting our sampling criteria had a positive BAC, as did 69 percent of drivers killed in single vehicle crashes nationwide in 1985.[8] Alcohol use was associated with increased injury severity. It is likely that alcohol use contributes to these deaths in two ways: by increasing the likelihood that an immersion event will occur, and by impairing the ability to escape a sinking vehicle.

Finally, we have demonstrated that roadway curvature is an important environmental contributing factor for fatal motor vehicle immersions. Similar results have previously been described for fatal crashes involving roadside fixed objects[5] and single vehicle fatal rollover crashes.[9,10] Sites at high risk for future crash involvement can therefore be identified for environmental modification.

Placing guard rails along waterside roadways would substantially decrease the incidence of immersions. The guardrail now in use in the study area is a w-beam, blocked-out design. Field studies have demonstrated that this design is highly efficient at redirecting impacting vehicles, with a penetration rate of less than 15 percent.[11] The cost of installing this guard rail averaged $14.50 per linear foot in 1988,* or $76,560 to protect one side of a mile of roadway.

It is probably not cost-effective to install guard rails throughout an entire system of waterside roadways. Using a curvature criterion would permit resources to be focused on the most hazardous locations. Nearly half of high-risk locations would be protected by installing guard rails along sections of roadway with curves of 20° or greater over 1000 feet, while minimizing installation in low-risk areas.

ACKNOWLEDGMENTS

The authors thank Sacramento County Coroner C. R. Simmons and his staff for their willingness to make data available, and Barbara Claire for her assistance with the crash site investigations.

Drownings in Minnesota, 1980–85: A Population-Based Study

KATRINA HEDBERG, MD, PAUL D. GUNDERSON, PHD, CAROL VARGAS, MICHAEL T. OSTERHOLM, PHD, MPH, AND KRISTINE L. MACDONALD, MD

Abstract: We conducted a population-based study of drownings in Minnesota from 1980 through 1985. Five hundred and forty-one drownings (2.1 per 100,000 person-years) were identified from death certificates and from incident reports filed with the Minnesota Department of Natural Resources. Most drownings (334, 62 percent) occurred during summer months (May–August) and involved boating (42 percent) and swimming (35 percent) events. However, 62 drownings (11 percent) occurred during winter months (December–February) and primarily involved snowmobiles and motor vehicles (71 percent) breaking through ice on lakes and waterways. The risk of drowning, estimated by the ratio of drownings to number of water-related activities, was highest during March and April, when the ice on lakes and waterway surfaces is melting, and during October and November, when lake and waterway surfaces are starting to freeze. Drowning rates were highest for males (3.7 per 100,000 person-years), persons 15 to 25 years of age (3.3 per 100,000 person-years), and children less than 5 years of age (2.5 per 100,000 person-years). These data can be used to target prevention strategies, particularly in northern climates. (*Am J Public Health* 1990; 80:1071–1074.)

Introduction

Drowning is the third most common cause of fatal, unintentional injury in the United States; among children and young adults it is the second most common cause.[1] In 1984, drowning accounted for 4,444 deaths nationwide.* Yet detailed epidemiologic data are lacking for outdoor and recreational drownings in northern climates, where surface water is frozen for several months of the year.[2]

Minnesota is known as "The Land of 10,000 Lakes." Water covers 7,353 square miles or 9.2 percent of the state's surface area. Lakes and waterways provide the 4.2 million people who live in Minnesota with numerous recreational opportunities throughout the year, including swimming and boating in the summer and ice-fishing in the winter. The lakes and waterways are usually frozen from December through March.

We conducted a population-based study of drownings in Minnesota, with an emphasis on outdoor and recreational drownings. In addition to characterizing drowning victims, we examined data by season-specific activities associated with drowning.

Methods

A case of drowning was defined as an unintentional death due to submersion in water, that occurred to a Minnesota resident during 1980 through 1985. Deaths involving motor vehicles operated in or on a body of water were considered to be drownings. However, deaths involving motor vehicles that ran off the road into water were considered to be motor vehicle fatalities.

Data on drownings were obtained from two sources: death certificates maintained by the Minnesota Center for Health Statistics, and fatal injury reports filed with the Minnesota Department of Natural Resources. All death certificates in Minnesota are assigned an ICD-9 cause of death code by a certified nosologist. Death certificates assigned an ICD-9 code for drowning were reviewed. This included both boating (E830-E832) and non-boating fatalities (E910).

Law enforcement officials are required to investigate and file a report with the Department of Natural Resources on all fatal injuries that occur on Minnesota lakes and waterways (Minnesota Statute 361.24). These officials often use coroner reports in preparing their reports. These reports were reviewed, and information was obtained on the age and sex of the victim; the date, time, and location of the incident; the victim's activity at the time of drowning; the probable cause of the drowning; and history of alcohol use. Death certificates and Department of Natural Resources reports were manually matched by name, age, and address.

Drowning rates were calculated for the general population of Minnesota residents using population data extrapolated from the 1980 census. To estimate rates of outdoor and recreational drownings for the specific population-at-risk, we calculated the ratio of drownings to the estimated number of water-related activities. The annual number of water-related activities in which Minnesota residents participated was extrapolated from a random telephone survey of 6,000 households conducted by the Department of Natural Resources during a 12-month period, beginning in September 1985.** Each week, a sample of households was contacted and asked to report the age and sex of household members and the number of water-related activities in which each member had participated during the preceding week. (Information was collected on a number of activities, but not on hours of activity.) In addition, we reviewed records that the Department of Natural Resources has maintained since 1944 on the number of drowning deaths that have occurred in Minnesota.

Data were analyzed using standard univariate methods.[3] Years of potential life lost prior to age 65 were calculated.[4]

Results

Five hundred and forty-one drownings occurred to Minnesota residents during 1980 through 1985; 458 drownings (85 percent) were identified from death certificate review (ICD-9 codes E830-32 and E910) and 83 drownings (15 percent) were identified only from Department of Natural Resources reports (death certificates were retrieved for these drownings). These 83 deaths were coded as follows: 35 (42 percent) were assigned the ICD-9 code for drownings which reflects accidental or purposely inflicted cause undetermined (E984); 32 (39 percent) were assigned the code for motor vehicle fatalities (E820-25); and 16 (19 percent) were assigned other ICD-9 codes including cardiac arrests, diving accidents, falls and hypothermia.

Four hundred and ninety-one drownings (91 percent) occurred in Minnesota and 50 (9 percent) occurred out-of-state. Forty-three (86 percent) of the out-of-state drownings occurred in the states immediately adjacent to Minnesota or in areas with northern climates (Montana, Alaska, and Canada). The seasonal distribution for the out-of-state drownings was similar to the distribution of drownings which occurred in Minnesota. Five hundred drownings (92 percent) occurred outdoors or were related to recreation and 41 drownings (8 percent) occurred in bathtubs. Department of Natural Resources reports were completed on 404 (90 percent) of the 450 outdoor and recreational drownings that occurred in Minnesota.

Death Certificate Review

The 541 drownings identified represent an overall mean annual incidence of 2.1 drownings per 100,000 person-years. The annual incidence declined over the study period from 2.5 per 100,000 person-years in 1980 to 1.9 per 100,000 person-years in 1985. This finding is consistent with a decreasing trend in the annual incidence of drowning observed in Minnesota since 1944. The drownings that occurred during the study period represent 17,853 years of potential life lost before age 65 (33 years lost for each death).

The majority of drownings (334, 62 percent) occurred during the summer months, May through August, when outdoor and recreational activities peak (Figure 1). However, 62 drownings (11 percent) occurred during the winter months, December through February, when lakes and waterways are frozen, and water-related activities are low. The risk of drowning, estimated by the ratio of drownings to number of water-related activities, was highest during spring and fall months (Figure 1).

Overall, 447 drownings (83 percent) occurred in males (Figure 2). The mean annual incidence for males was 5.3 times higher than that for females (3.7 versus 0.7 per 100,000 person-years, respectively). Incidence rates were highest for persons 15 to 30 years of age and for person less than 5 years of age (3.3 and 2.5 per 100,000 person-years, respectively). For the age group 15 to 30 years, 91 percent of drownings occurred in males. For this age group, the rate for males was 10 times higher than the rate for females (5.2 versus 0.5 per 100,000 person-years, respectively). The ratio of number of drownings to number of water-related activities for males was 3.3 times higher than the ratio for females (13.7 versus 4.2 per 1,000,000 activities, respectively).

The drowning rate for persons 15 to 49 years of age decreased significantly over the six-year study period ($p < 0.001$, chi-square test for trend). However, rates for persons less than 15 years of age and for persons greater than or equal to 50 years of age did not show a similar decrease ($p = 0.22$, and 0.82, respectively, chi-square test for trend).

Department of Natural Resources (DNR) Incident Report Review

DNR report forms were completed for 404 of the outdoor and recreational events. Of these, 382 (95 percent) occurred in a lake, pond, river, or stream, and 18 (4 percent) occurred in a swimming pool.

Table 1 shows the type of activity in which victims were engaged at the time of drowning. Swimming and boating were the most common activities during the summer, driving a vehicle on ice was the most common activity during the winter, while boating and falling from a bank into a body of water were common activities during the fall and spring.

Type of activity also varied by age group. For all ages combined, 66 drownings (16 percent) were due to falling from land, pool-side, or through ice into a body of water. However, for the 29 drownings that occurred in children <5 years of age, 22 (76 percent) were due to falling into a natural body of water or through ice, and three (10 percent) were due to falling into swimming pools. For the 21 drownings that occurred in persons ≥60 years of age, all were due to falling into water from land, pool-side, or through ice.

One hundred and thirty-five of the 404 drownings (33 percent) involved boating incidents. Table 2 shows the probable cause of boating-related drownings and the use of a

personal flotation device. Only 13 drownings (10 percent) occurred while such a device was being used.

History of alcohol use was noted on 242 reports (60 percent); three (6 percent) of 54 persons less than 15 years of age and 109 (58 percent) of 188 persons more than 15 years of age were reported as having consumed alcohol at the time of the event.

Discussion

The mean annual incidence of drowning in Minnesota during 1980 through 1985 (2.1 per 100,000 person-years) was lower than the 1984 incidence of drowning nationally (2.3 per 100,000 person-years),[5] and lower than the incidence in Georgia from 1981 through 1983 (3.2 per 100,000 person-years),[6] New Mexico from 1975 through 1980 (4.3 per 100,000 person-years),[7] North Carolina from 1980 through 1984 (3.2 per 100,000 person-years),[8] and Los Angeles County from 1976 through 1984 (2.4 per 100,000 person-years).[9] This probably reflects the fact that the peak season when people are participating in outdoor water activities is shorter in Minnesota where lakes and waterways are usually frozen for several months of the year.

We believe that a population-based incidence rate provides an accurate estimate of the risk of drowning and can be compared to population-based rates in other states. Yet, population-based rates assume that every resident in the state is at equal risk of drowning. The ratio of drownings to the number of water-related activities provides an estimate of the risk of drowning for the specific population that participates in water-related activities. The importance of this estimate is illustrated by the seasonal trends in drowning rates.

Previous investigators have noted that the incidence of drowning has marked seasonal variation.[1,10] In Minnesota, as in other states, most drownings occurred during the summer. However, if the risk of drowning is estimated by the ratio of drownings to number of water-related activities, the risk was highest during the spring and fall months, when the ice on the lakes is starting to freeze or thaw and likely to be unsafe. In addition, a submersion incident may be more likely to result in a fatality during the non-summer months due to the increased risk of hypothermia. Thus, this increased risk is probably specific to areas where surface water freezes during the winter.

Investigators in Hawaii and California found that the majority of drownings in these areas occurred in swimming pools.[9,11,12] However, we found that 95 percent of drownings in Minnesota occurred in lakes and waterways and only 4 percent occurred in swimming pools. Even in children less than 5 years of age, only three drownings occurred as a result of falling into swimming pools. Minnesota residents may use swimming pools less than residents of more southern climates because most people have access to natural bodies of water and because of the relatively short season in which people can swim outdoors. Therefore, prevention measures such as requiring all swimming pools to be fenced in, which have proved to be effective in other areas,[13] may have only limited impact in areas similar to Minnesota.

Our data showed that males, children, and young adults had the highest rates of drowning, a finding consistent with several past studies.[6–12,14–16] Comparing population-based rates, the incidence in males was 5.3 times the incidence in females. However, if the risk of drowning is estimated by the ratio of drownings to the number of water-related activities, the risk for males was only 3.3 times the risk for females. Thus, some of the excess risk seen in males may be due to increased time spent participating in water-related activities.

Behavioral factors which may put people at increased risk of drowning include alcohol consumption[16–19] and the nonuse of a personal flotation device. Although more than half of the Minnesota Department of Natural Resources reports completed for persons over 15 years of age listed alcohol consumption as contributing to the drowning, we do not know the number of people consuming alcohol that did not drown. Also, although only 10 percent of boat-related drownings occurred while a flotation device was being used, we do not know how many people who were wearing such devices did not drown, or how many drownings were avoided by people wearing such devices. Therefore, although our data suggest that alcohol consumption and the nonuse of a flotation device may increase the risk of drowning, we are unable to evaluate the exact contribution of these possible risk factors.

Although the overall rate of drowning in Minnesota decreased during the study period, only the rate in persons 15 to 49 years of age showed a significant decline. Risk-taking behavior may have contributed more to drownings in this age group than in other age groups, and may have been more amenable to current intervention strategies. The decrease in the incidence of drowning deaths may also have been a result of improved medical treatment. However, we were unable to evaluate this due to the lack of data on near-drownings.

To design, implement and evaluate injury intervention strategies, accurate surveillance data on injuries are needed.

Previous investigators have questioned the accuracy and usefulness of death certificates for obtaining selected mortality statistics.[20] In our study, 15 percent of the drownings were identified from the Department of Natural Resources reports and would have been missed if we had relied solely on death certificate review. We did not include death certificates assigned ICD-9 code E-984 in our initial review because we wanted to exclude suicides and homicides from the study. However, by examining information from the Department of Natural Resources reports, we were able to include those deaths which were unintentional. In addition, one-third of the drownings identified from the Department of Natural Resources reports had been assigned an ICD-9 code for a motor vehicle fatality. We chose to include only those deaths in which the vehicle was operated on an ice-covered body of water and exclude those in which the vehicle had run off a road into water, assuming that different risk factors may have been involved. Such information on the circumstances surrounding the events was available from the Department of Natural Resources reports but was lacking on most death certificates. This information is vital to understanding the causes of drowning and can be used to target further prevention strategies.

Society for Disability Studies Issues Call for Papers

The Society for Disability Studies has issued a call for papers for its fourth annual convention, to be held June 19–22, 1991, in San Francisco, California. Possible themes for paper presentations may include research issues of policy, history, sexuality, law, culture, statistics, methods, politics, media, literature, gender, self-image, cross-cultural, family, and related topics. Organized panels are encouraged, but they must be multidisciplinary and cross disability. Proposals for roundtables are also encouraged, and they should attempt to bring together participants with similar research interests.

The deadline for submission of abstracts is January 15, 1991. Please send two copies of a two-to-three page abstract to: Professor David Pfeiffer, Department of Public Management, School of Management, Suffolk University, Boston, MA 02108. Tel: (617) 573-8317.

The Society for Disability Studies is a multidisciplinary organization dedicated to the development of an appreciation and understanding of disability-related theory and its application as well as an agenda for further research in this area. For information about the Society, or its periodical, *Disability Studies Quarterly*, contact Professor Irving Kenneth Zola, Department of Sociology, Brandeis University, Waltham, MA 02254-9110. Tel: (617) 736-2644.

A Multifocal Outbreak of Hepatitis A Traced to Commercially Distributed Lettuce

LISA S. ROSENBLUM, MD, MPH, IRENE R. MIRKIN, MD, DAVID T. ALLEN, MD, SUSAN SAFFORD, MD, AND STEPHEN C. HADLER, MD

Abstract: From February 1 through March 20, 1988, 202 cases of hepatitis A were reported in and around Jefferson County, Kentucky. The epidemic curve indicated a common-source exposure. However, there was no apparent single source of exposure from a restaurant, or community gathering; nor was there a geographic clustering by residence. Cases were mainly adults 20–59 years old (89 percent); 51 percent were female. A case-control study using neighborhood controls found that factors associated with hepatitis A were: having eaten downtown (odds ratio [OR] = 4.0) and having dined at any one of three restaurants (OR = 21.0). Case-control studies of patrons of two of these restaurants found that eating green salad was strongly associated with acquiring hepatitis A: OR = 11.6 and OR = 4.4. The three implicated restaurants accounted for 71 percent of the cases. All three restaurants were supplied by the same fresh produce distributor; however, investigation suggested that contamination most likely occurred prior to local distribution. This outbreak of hepatitis A is the first in the United States apparently associated with fresh produce contaminated before distribution to restaurants, and raises important public health issues regarding the regulation of fresh produce. (*Am J Public Health* 1990; 80:1075–1080.)

Introduction

In 1988, 26,600 cases of hepatitis A were reported in the United States.[1] During 1983–88 the incidence of reported cases of hepatitis A increased from 9.2 to 10.9 per 100,000 population, representing the first increase in hepatitis A in more than a decade.[1–3] An estimated 1,000 cases are associated with suspected food- or water-borne outbreaks of hepatitis A each year.[3]

Previous investigations of common-source food-borne outbreaks of hepatitis A have described unifocal outbreaks in which a single location of food consumption (such as a restaurant) was the site of the outbreak; generally, a food handler, recently infected with hepatitis A virus (HAV) and working at that site, was implicated as the source of contamination of the food.[4–6] There have also been reports of outbreaks involving more than one restaurant; however, a food handler was implicated as the source of contamination at each restaurant.[4,7] The major multifocal food-borne outbreaks of hepatitis A due to the contamination of food before distribution to a restaurant have involved shellfish harvested from contaminated bays.[8,9] Reports from the United Kingdom have suggested that certain commercially processed foods (such as frozen raspberries) may have been associated with the transmission of HAV.[10,11]

This is the first report of a hepatitis A outbreak in the United States associated with unprocessed fresh produce contaminated before distribution to restaurants.

Methods

From February 1 through March 20, 1988, a widespread outbreak of hepatitis A affected 202 residents of Jefferson County, Kentucky (1986 intercensal population estimate, 681,066) and the surrounding area. The Louisville-Jefferson County Board of Health, the Kentucky Department of Health, and the Centers for Disease Control initiated a series of investigations to determine the risk factors for the transmission of HAV.

Case Identification

A case was defined as a person who had onset of an illness compatible with viral hepatitis from February 1 through March 20, 1988, and either a positive serologic test for immunoglobulin M (IgM) antibody to HAV (IgM anti-HAV) or a physician diagnosis of hepatitis A. Cases were ascertained through reports by physicians to the Louisville City-Jefferson County Health Department. Serologic testing for IgM anti-HAV was performed by private and hospital-based laboratories in Louisville. All cases were interviewed by telephone to obtain demographic information, date of onset and clinical course of illness, work location, and place of residence.

Community Food and Water Exposure Study

Because the epidemic curve indicated a common source of exposure, a case-control study using neighborhood controls was performed to identify the location of the common source of food or water in the community. A random sample of cases who resided in Jefferson County were matched with controls by neighborhood and by age within 10 years. One control who lived within 10 houses in either direction from each case was selected randomly by using a reverse telephone directory. Eligible controls had no history of hepatitis; no undiagnosed illness during February or March, with any two of the following symptoms: jaundice, nausea, vomiting, and abdominal discomfort; no receipt of immune globulins within the past six months; and no household or sexual contact with a person with hepatitis A since January 15, 1988. Cases and controls were interviewed by telephone to obtain demographic information, history of food and water exposures at home and work, and exposures at restaurants, stores, parties, and community gatherings during January 15–31.

Restaurant Food Exposure Studies

Because the neighborhood study found that eating at any one of three restaurants was associated with acquiring hepatitis A, two of the restaurants (A and B) were selected as sites for the investigation of the source of HAV. Restaurants

Address reprint requests to Lisa S. Rosenblum, MD, Medical Epidemiologist, Hepatitis Branch, Division of Viral Diseases, Center for Infectious Diseases, Centers for Disease Control, Atlanta, GA 30333. Dr. Hadler is also with that Branch; Dr. Mirkin is with the Division of Field Services, Epidemiology Program Office, CDC; Dr. Allen is with the Louisville-Jefferson County Board of Health, Louisville, KY; Dr. Safford is with the Epidemiology Program Office, CDC. This paper, submitted to the Journal November 27, 1989, was revised and accepted for publication March 28, 1990.

A and B were selected because they accounted for most of the cases, and no case had patronized both restaurants. Restaurant A, located in a downtown professional district, was primarily a lunch business, serving sandwiches, chef salads, and soup. Restaurant B, located in the outskirts of the city, was primarily a dinner restaurant, with standard American fare and a salad bar.

The period of risk of exposure at these restaurants was considered to be January 15–31, one month (the average incubation period for HAV) preceding the period of peak case incidence (February 15–28). Evaluation of the dates of exposure of patrons who ate only once at one of these restaurants (A or B) and ate at no other restaurants in Jefferson County during the month preceding their illness confirmed that January 15–23 was the period of high risk.

For each restaurant study, eligible cases and controls had dined at the designated restaurant (A or B) during January 15–31; controls also had to meet the four eligibility criteria described for controls in the neighborhood study. For the study of restaurant A patrons, unmatched controls were randomly selected from a list of coworkers of each case. For restaurant B, controls were meal companions of the cases. Telephone interviews of cases and controls obtained demographic information and history of food consumption, including the frequency of eating particular foods.

Investigating the Source of Contamination

Based on the results of the restaurant studies, which implicated fresh produce obtained from a single local distributor, the Food and Drug Administration traced the source of shipments of food received by the distributor. In collaboration with the Louisville-Jefferson County Board of Health, the Louisville Water Company evaluated the water supply system.

Statistical Methods

In the community case-control study, exact confidence limits for the odds ratios were calculated by using standard procedures for the binomial distribution.[12] MCSTRAT (a procedure in Statistical Analysis Systems), which is designed for matched case-control data, was used to estimate the variances of the odds ratios in multivariate analysis.[13] For the restaurant case-control studies, variances for the odds ratios were estimated by using the method described by Cornfield.[12]

Results

Outbreak

From February 1 through March 20, 1988, 202 reported cases of hepatitis A met the case definition; 99 percent were tested and confirmed as IgM anti-HAV positive. Cases included 172 Jefferson County residents, and 30 others who had histories of exposures in Jefferson County during the last two weeks in January.

During the 13 months preceding the epidemic, only 12 cases of hepatitis A had been reported in Jefferson County. During the epidemic, there was no increase in the number of cases reported in any of the surrounding counties in Kentucky or Indiana, except for the cases who had known exposures in Jefferson County.

The epidemic curve, with a sharp peak and most of the cases occurring within the two-week period, suggested a common-source exposure (Figure 1). There was no apparent single source of exposure from a restaurant or community gathering and no geographic cluster by location of residence; only seven families had more than one case. Cases clustered

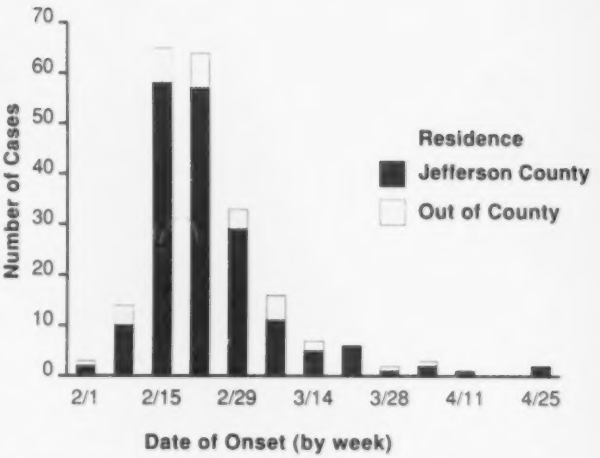

FIGURE 1—Hepatitis A Cases by Date of Onset of Symptoms, Jefferson County, Kentucky, February 1–April 30, 1988

by work location, with 33 percent of the cases working in the downtown area.

Of the cases residing in Jefferson County, the mean age was 38 years (range: 1 to 75 years), 89 percent were 20 to 59 years old, and 51 percent were female. The overall attack rate was 25 cases per 100,000 residents of Jefferson County. The highest attack rate was for adults 20 to 59 years old (40 cases per 100,000 persons), with the highest age-specific attack rate occurring among persons 40 to 49 years old (62 cases per 100,000). Of the 172 cases, 91 percent were jaundiced and 23 percent were hospitalized. HAV infection may have contributed to two deaths (for a case-fatality ratio of 1 percent), including a 60-year-old man who required a liver transplant five months after the onset of illness and died two months later, and a 53-year-old man with a history of alcohol abuse, who died three weeks after onset of illness.

Community Food and Water Exposures

In the study of community food and water exposures, 30 neighborhood case-control pairs were interviewed. A comparison of cases and their matched controls indicated that 70 percent of the pairs had similar levels of income and education, and all were White and non-Hispanic.

Exposures associated with acquiring hepatitis A in univariate analysis included (Table 1) working downtown (odds ratio [OR] = 5.0), having eaten downtown (OR = 4.0), having dined at any one of three (A, B, or C) restaurants (OR = 21.0), and having eaten salad at any restaurant (OR = 6.0). Two of the three implicated retaurants were located downtown. The association between acquiring hepatitis A and having dined at these three restaurants persisted when results were adjusted separately for history of work downtown, and for potential confounders (e.g., income and education).

Restaurant Food Exposures

Restaurant A: In the study of patrons of restaurant A, 38 (100 percent) of the eligible cases were interviewed, and 36 fellow office workers were interviewed as controls. The study found that eating green salad was associated with an 11.6-fold increased risk of acquiring hepatitis A (Table 2). Consumption of other foods was not associated with an increased risk of disease. The risk of acquiring hepatitis A increased as the frequency of consumption of green salads increased from a

Dressing (if ate salad)	26/32 (81)	11/11 (100)	0.0	0.0, 2.7
Garnish on sandwich (among nonsalad eaters)	6/6 (100)	13/24 (54)	∞	0.8, ∞
Green salads, or garnish on sandwich	38/38 (100)	24/36 (67)	∞	0.0, ∞

1.0-fold risk for those never ordering salad, to an 8.0-fold risk for those sometimes ordering salad, to an 18.0-fold risk for those always ordering salad ($p < .001$, Mantel-Haenszel trend test).

Among those not eating salad, there was an association between disease and consumption of a sandwich with a lettuce or a tomato garnish ($p = .046$). All cases ordered either a green salad or a sandwich with a garnish. The high correlation between ordering a lettuce and a tomato garnish on a sandwich (.74) precluded analysis of the risk of disease associated with a single vegetable.

Restaurant B: In the study of patrons of restaurant B, 48 (100 percent) of the eligible cases and 43 controls were interviewed. Results indicated that eating salad from the salad bar was associated with a 4.4-fold risk of infection and that ordering either the salad bar or a tossed salad with a main dish was associated with a 6.7-fold risk of disease (Table 3). No other menu item was associated with increased risk.

Patrons of restaurant B were interviewed about the consumption of specific food items from the salad bar; however, no single item could be implicated. The high degree of correlation between ordering two given items from the salad bar precluded further analysis of the risk associated with a single salad bar item. Among those eating salad, salad dressing was not associated with increased risk of infection.

Tracing the Source of Contaminated Fresh Produce

During January 15–30, 71 percent of the cases reported exposures at any one of the three implicated restaurants. The peak of the epidemic curve associated with each of these restaurants occurred the same week. Three of the reported cases were food handlers at restaurant A, and one was a food handler at restaurant B; however, the dates of onset of illness among these employees were within the main part of the epidemic curve, not consistent with transmission to their customers, and the employees did not work at other restau-

*If a respondent did not answer a question, the respondent was excluded from analysis for that exposure.

rants. The remainder of the employees at restaurant A were tested and were negative for IgM anti-HAV.

The epidemiologic studies implicated salad as the vehicle of transmission, and results of the study at restaurant A suggested that either lettuce or tomatoes were the contaminated produce. Lettuce was considered the most probable vehicle of transmission because all the implicated types of salads contained lettuce, and because lettuce, as compared with other produce such as tomatoes, is harder to clean thoroughly by rinsing. Since all three of the implicated restaurants served iceberg lettuce, and two of the three restaurants served only iceberg lettuce, the suspected vehicle was iceberg lettuce.

All three restaurants were supplied by the same local fresh produce distributor. (Less than 5 percent of food service establishments in Jefferson County were supplied by the implicated distributor.) At the implicated distributor, no hepatitis A cases were identified among the workers, and the handling of produce was minimal. Produce was generally not unpacked from the crates in which it was shipped and not washed or processed. Therefore, contamination most likely occurred before local distribution.

Shipments of iceberg lettuce that would have been received by the local distributor in Louisville January 11–16 were traced to four domestic suppliers; however, no information was available regarding the farm source of lettuce provided by these suppliers. Just before the outbreak in January of 1988, the importation of Mexican iceberg lettuce increased 10-fold[14] because of drought in the Summer of 1987 in the United States (Figure 2). Mexican iceberg lettuce was observed in Louisville by local United States Department of Agriculture (USDA) inspectors during the last two weeks in January (J. Sullivan, Louisville-Jefferson County Board of Health, personal communication, March 1988). However, there is no information available to determine if Mexican imported produce was received by the local distributor or its suppliers.

Investigation of the Water System

The results of bacteriologic sampling of the water distribution system were within normal limits during the months of January and February 1988. No relationship was found between the geographic distribution of cases and the water distribution system or events such as water company construction, repair, and unusual flow disturbances.

Discussion

This common-source outbreak of hepatitis A was unusual in that there was no single source of exposure from a restaurant or community gathering, nor was there geographic clustering by neighborhood. The epidemic curve, with a sharp peak and most of the cases occurring within a two-week period, indicated a common source of exposure. The age distribution (88 percent of the cases in adults 20 to 59 years old) was atypical of community person-to-person spread and suggested that the persons primarily affected by the epidemic were a "working" cohort.

Case-control studies found that the outbreak was due to contaminated salad served by several restaurants. Because serum specimens of controls were not tested, it is possible that some controls may have been immune or asymptomatic cases. For this possibility to have accounted for the observed associations, there would have to have been an association between exposure, and either immunity or expression of illness. However, without such an assumption (for which there is no basis), the presence of immune controls or asymptomatic cases would tend to produce a conservative estimate of the associations observed.

This is the first report of an outbreak of hepatitis A in the United States associated with a vegetable product which was contaminated prior to distribution to restaurants. At least three restaurants were involved in the outbreak, each accounting for no more than one-third of the cases. Foodhandlers at the restaurants were unlikely to have been the source of the epidemic for two reasons. First, no index case was identified at any of the restaurants. Although serosurveys were not performed at all restaurants, most (76–97 percent) of HAV infections among adults are symptomatic.[14] Second, because the epidemic curve was unimodal, it was unlikely that foodhandlers at each restaurant could have accounted for transmission of HAV to their clientele. Contamination of the produce most likely occurred before local distribution to the restaurants, as there was no hepatitis A case identified among the workers, and there was minimal handling of produce at the local distributor which supplied the three restaurants.

The most likely vehicle of transmission was iceberg lettuce; however, the exact farm source of contaminated lettuce could not be determined. There was no evidence of concurrent outbreaks in the United States associated with lettuce contaminated before local distribution, and the focal nature of the outbreak suggested that either a limited supply of lettuce grown in the United States or imported lettuce had been contaminated. During the peak period of importation in January 1988, Mexican lettuce accounted for only 1 percent of the total US consumption,[15] with any single grower accounting for a small fraction of the total. Contamination of the produce may have occurred in the fields from contaminated water used for growing or irrigation, or from the use of night soil (excrement removed from a cesspool or privy and used as fertilizer). Alternatively, contamination may have occurred during the shipping process if riders were transported in the back of the truck with the produce.

Lettuce contaminated before distribution to food-service facilities also has been associated with two recent large epidemics of shigellosis.[16,17] In these outbreaks, contamination was believed to have occurred in the field or a

warehouse,[16] and in a food-processing plant.[17] Laboratory studies have demonstrated the survival of HAV (in feces) and *Shigella* (in a variety of nonacidic foods) for several weeks at 25 °C.[18,19] These outbreaks underscore the importance of proper sanitation facilities, and good hygiene of workers at each step of the food handling chain.

The timing of the marked increase in imported lettuce in relation to this outbreak, which was associated with fresh produce contaminated before local distribution, raises public health concerns regarding the regulation of imported fresh produce. The purity of water supply used in growing, availability of sanitation facilities to workers, and possible use of night soil by foreign lettuce growers, have not been determined. Imported lettuce is not routinely examined for evidence of fecal contamination at the port of entry to the United States. Imported unprocessed lettuce is exempt from US Customs requirements to label the country of origin on the imported article itself.[20] Although the country of origin must be marked on the outermost container of lettuce that reaches the ultimate purchaser,[20] containers such as supermarket bins and rubberbands holding fresh produce are not subject to marking; if produce should reach the ultimate purchaser without a container, there is no requirement to display the country of origin (M. Amernick, Esq., US Customs, personal communication, October 1989).

Moreover, because there are no federal requirements to label the name of the farm on either imported or domestic lettuce that reaches the ultimate purchaser, and because more than one farm can supply any supplier, it may be impossible to trace lettuce to the growing site during an outbreak, as was the case in this epidemic.

During 1983–88, for the first time in over a decade, there has been a nationwide increase in reported cases of hepatitis A[1–3]; the cause of the increase is not known. This multifocal epidemic of hepatitis A is the first report of an outbreak in the United States associated with a vegetable contaminated before distribution to restaurants, and raises important public health concerns regarding the regulation of both domestic and imported fresh produce.

ACKNOWLEDGMENTS

The authors wish to thank the following persons for their assistance in the investigation of the outbreak: James Sullivan, Ellen Van Nagell, Clark Bledsoe, Ellen Buchart, Sue Wulf, and Eve Burden (Louisville-Jefferson County Health Department); Drs. Michael Moser and Reginald Finger (Health Department of Kentucky); and Robert Hudson and Patrick Pouzar (Food and Drug Administration). The authors also wish to thank Marvin Amernick (US Customs) for providing information regarding US Customs regulations.

Impact of the Human Immunodeficiency Virus Epidemic on Mortality Trends in Young Men, United States

James W. Buehler, MD, Owen J. Devine, Ruth L. Berkelman, MD, and Frances M. Chevarley, PhD

Abstract: Following a long-term decline, death rates in men 25–44 years of age increased from 212 deaths/100,000 in 1983 to 236 deaths/100,000 in 1987. To assess the impact of human immunodeficiency virus (HIV) infections on this trend and to identify causes that are increasing in association with the HIV epidemic, we analyzed national mortality statistics and compared death rates in states with high and low incidence of acquired immunodeficiency syndrome (AIDS). In 1987, there were 10,248 deaths with HIV infection, AIDS, or conditions in the AIDS surveillance definition assigned as the underlying cause, representing 11 percent of deaths for men in this age group compared to less than 1 percent in 1980. In addition, deaths with other underlying causes, such as other infections, drug abuse, and unknown/unspecified causes, had diverging and higher rates in states with high versus low AIDS incidence. In the absence of deaths due to HIV/AIDS and excess deaths due to these associated conditions, we estimate that death rates for men 25–44 years of age would have been 201–209/100,000 in 1987. For 1987, approximately 70–90 percent of HIV-related deaths were reported through national AIDS surveillance. The HIV epidemic has led to a reversal in mortality trends and to increases in various causes of death for young men. (*Am J Public Health* 1990; 80:1080–1086.)

Introduction

Following a long-term decline, death rates in men 25–44 years of age have begun to increase in the 1980s in the United States (Figure 1). This reversal of mortality trends has coincided with the epidemic of human immunodeficiency virus (HIV) infections and acquired immunodeficiency syndrome (AIDS), which has predominantly affected young men.[1] Deaths due to HIV infection have emerged as a leading cause of years of potential life lost,[2,3] and provisional mortality data from the national vital statistics system indicated that HIV infection ranked fifteenth in 1988 among all causes of death in the United States.[4]

To measure the impact of the HIV epidemic on mortality in young men, we used national mortality data to identify causes of death that are increasing in association with the HIV epidemic and to estimate the number of HIV-related deaths. In these analyses, we examined death rates for a broad spectrum of causes. We focused not only on HIV infection and diseases in the surveillance definition for AIDS but also on other infections and malignancies which have had a suggested link to HIV. In addition, to assess the completeness of national AIDS surveillance, we compared our estimate of HIV-related deaths from vital statistics to mortality data from AIDS case reporting.

Methods

Death Rates 1980–1987

We calculated death rates (deaths/100,000 population) using computer tapes prepared by the National Center for Health Statistics (underlying and multiple causes of death) and the Bureau of the Census.[5,6] We limited our analyses to men, ages 25–44 years, who were United States residents (excluding territories). To identify causes of death associated with HIV infection, we compared mortality trends for four groups of states ranked by AIDS incidence rates, using data from national AIDS surveillance.[7] The highest group (California, Florida, New Jersey, New York, and the District of Columbia) accounts for 59 percent of all AIDS cases reported in men 25–44 years of age, while the lowest group (21 states) accounts for 5 percent of cases. We calculated crude, race-, and age-adjusted death rates. Adjusting for race did not affect the identification of causes that increased more rapidly in states with highest AIDS incidence, and adjusting for age had virtually no effect on comparisons by year or state group. Thus, we present only death rates unadjusted by race or age.

We grouped cause-of-death codes from the Ninth Revision of the International Classification of Disease (ICD-9)[8] into the following categories: HIV infection or AIDS (ICD-9 No. 279.1 for 1980–86, category *042–*044 for 1987*, see below); diseases included in the national surveillance case definition for AIDS (*Pneumocystis carinii* pneumonia, other AIDS-defining infections, Kaposi's sarcoma, non-Hodgkin's lymphomas, encephalopathy, wasting syndrome)[9,10]; other immune deficiency (excludes conditions assigned ICD-9 No. 279.1 in 1980–86, see below); infections not in the AIDS surveillance definition (pneumonia and influenza, septicemia, pulmonary tuberculosis, heart, central nervous system, all other infections); blood disorders (congenital coagulation defects, others); selected cancers with a postulated link to HIV infection (oral-pharyngeal, anal-rectal, other gastroin-

*The notation "category *042–*044" indicates that these are supplemental codes and not part of ICD-9.[9]

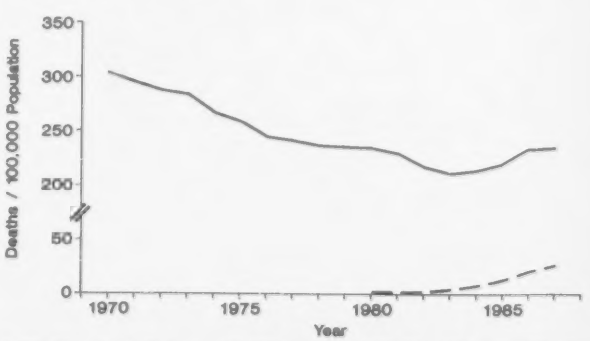

FIGURE 1—Death Rates per 100,000 Population 1970–87 (solid line), and Death Rates per 100,000 for HIV/AIDS and Conditions in AIDS Surveillance Definition, 1980–87 (broken line), Men 25–44 Years of Age, United States

Co-authors Devine and Dr. Berkelman are also with that Division at CDC; Dr. Chevarley is with the Office of Vital and Health Statistics, National Center for Health Statistics, Hyattsville, MD. This paper, submitted to the Journal October 10, 1989, was revised and accepted for publication January 31, 1990.

testinal cancers, Hodgkin's lymphoma)[11–19]; lung cancer, other cancers; injuries (suicide, homicide, unintentional injuries); drug abuse; other system disorders exclusive of above causes (endocrine/metabolic, mental/nervous, cardiovascular, respiratory, digestive, genitourinary, others); and unknown/unspecified causes.**

Beginning in 1983, a pre-existing ICD-9 code (ICD-9 No. 279.1, "deficiency of cell-mediated immunity") was adapted for HIV/AIDS and used through 1986.[20,21] In 1987, a more detailed set of codes (categories *042–*044) for HIV/AIDS was introduced, along with new procedures for assigning HIV/AIDS as an underlying cause.[9,22] In 1986, 52 percent of deaths among men 25–44 years of age which had any listing of HIV/AIDS on death certificates had HIV/AIDS assigned as the underlying cause; in 1987 this increased to 90 percent. For example, a death certificate that mentioned both HIV/AIDS and other diagnoses would be more likely to have HIV/AIDS classified as the underlying cause in 1987 than in 1986. We sought to minimize this discontinuity by considering HIV/AIDS and conditions in the AIDS definition as a single category.

We used the Taylor series method to calculate 95 percent confidence intervals (CIs) for ratios of death rates in 1987 compared to 1980.[23]

Estimate of the Number of HIV-related Deaths, 1987

To estimate the number of HIV-related deaths in 1987, we first determined the number of deaths with certificates that mentioned HIV/AIDS on multiple-cause listings. Among all other deaths, we next considered those with underlying causes identified in the above analyses as increasing in association with the HIV epidemic. For each of these causes, we defined baseline trends by fitting a least median of squares line to the logarithm of death rates for 1970–80.[24] Using this exponential decay model, we then estimated by extrapolation death rates and the number of deaths that would have occurred in 1987 (expected deaths) if baseline trends had remained unchanged. Because data for causes of death were based on a 50 percent sample for some states in 1972, we excluded 1972 from our calculations. Because a new version of the ICD was introduced in 1979, our model included a shift parameter representing the discontinuity that occurred from 1978 to 1979. For some causes, baseline rates during the 1970s were stable or essentially zero or had no consistent trend. When this occurred, we used rates in 1980 as the baseline for estimating expected deaths in 1987 (Table 3). We then calculated excess deaths as the difference between observed deaths (excluding those with certificates that mentioned HIV/AIDS) and expected deaths.

**A listing of codes is available on request from the lead author.

Results

Overall Trends

Deaths with HIV/AIDS or one of the conditions in the AIDS definition listed as the underlying cause increased from 583 (1.9 per 100,000 population) in 1980 to 10,248 (26.6/100,000) in 1987 for men ages 25–44 years in the United States (Figure 1). Such deaths represented 0.8 percent of 73,652 deaths to men ages 25–44 years in 1980 and 11.3 percent of 91,082 deaths in 1987. From 1980 to 1983, total death rates for young men declined from 235.8/100,000 to 212.1/100,000, respectively, and then rose 10 percent to 236.1/100,000 in 1987, returning to a level similar to the rate in 1980.

Among deaths due to HIV/AIDS or conditions in the AIDS definition, the distribution of causes shifted from 1980 to 1986, reflecting the emergence of HIV (Table 1). For example, non-Hodgkin's lymphomas accounted for over two-thirds of such deaths in 1980 but less than 10 percent in 1986. The distribution shifted again in 1987, reflecting implementation of new categories for HIV/AIDS (Table 1). For example, the number of deaths with conditions in the AIDS definition (e.g., *Pneumocystis carinii* pneumonia, Kaposi's sarcoma) assigned as the underlying cause declined from 1986 to 1987, while deaths assigned HIV/AIDS as an underlying cause increased sharply.

Of the 1,381 deaths with conditions in the AIDS definition (but not HIV/AIDS) assigned as the underlying cause in 1987 (Table 1), 136 (10 percent) also mentioned HIV/AIDS on multiple cause listings. In addition to the 8,867 deaths assigned HIV/AIDS as the underlying cause in 1987, there were 979 deaths with HIV/AIDS listed on death certificates but not assigned as the underlying cause. Among these 979 deaths, leading underlying causes were: infections not included in the AIDS definition, 25 percent; conditions in the AIDS definition, 14 percent; drug abuse, 9 percent; cardiovascular disorders (excluding infections and "cardiac arrest"), 8 percent; and lung cancer, 6 percent.

TABLE 1—Deaths with underlying Cause Including HIV/AIDS or Conditions in the AIDS Surveillance Definition, Men 25–44 Years of Age, United States, 1980, 1986, and 1987

Underlying Cause of Death	Number of Deaths			Percent		
	1980	1986	1987	1980	1986	1987

Death Rates and State AIDS Incidence

As expected, death rates for HIV/AIDS or for conditions included in the AIDS surveillance definition increased more in states with the highest AIDS incidence compared with other state groups, and by 1987 ranged from 56.7/100,000 (5,922 deaths) in the five states with the highest AIDS incidence to 8.8/100,000 (701 deaths) in the 21 states with the lowest AIDS incidence. In addition to conditions in the AIDS definition, five other categories for underlying cause-of-death had a divergence in rates from 1980 through 1987 for different state groups: infections not included in the AIDS definition, unknown/unspecified causes, drug abuse, blood disorders other than congenital coagulation defects, and other immune deficiency (Table 2). Mortality trends for the first three of these causes are shown in Figure 2 for states with the highest and lowest AIDS incidence (rates in states with intermediate AIDS incidence were intermediate). For one of these underlying causes, drug abuse, the death rate declined slightly (8.2 to 7.4/100,000) from 1986 to 1987 in the states with the highest AIDS incidence (Figure 2C); however, when multiple cause-of-death listings were used to include deaths with any mention of drug abuse, death rates for drug abuse increased in these states from 1986 to 1987 (19.0 to 22.4/100,000). This difference in trends between underlying and multiple causes-of-death appears to reflect a shift from 1986 to 1987 in the selection of HIV/AIDS or drug abuse as the underlying cause when both are listed on death certificates. For one other category, respiratory conditions (excluding respiratory infections), rates increased more in the highest AIDS incidence states by 1987 (Table 2), but the pattern of divergence for the years between 1980 and 1987 was less clear.

Among infections not included in the AIDS definition, death rates increased from 1980 to 1987 in each subcategory in states with the highest AIDS incidence, while no change, declines, or smaller increases were observed in states with the lowest AIDS incidence. Pneumonia and influenza was the subcategory with the highest death rate (predominantly "bronchopneumonia, organism unspecified" or "pneumonia, organism unspecified"), while the greatest relative increases were seen for septicemia and pulmonary tuberculosis (Table 2).

Death rates for drug abuse had a relative increase that was similar in the lowest AIDS incidence states as in the highest AIDS incidence states (Table 2); however, the absolute difference in rates between the highest and lowest AIDS incidence states widened from 2.7/100,000 in 1980 to 4.9/100,000 in 1987.

Among deaths due to blood disorders other than congenital coagulation defects, the increase in the highest compared with lowest AIDS incidence states was due primarily to unspecified coagulation defects, thrombocytopenia, and agranulocytosis. Among deaths due to non-infectious respiratory conditions, this increase was observed for deaths due to "pulmonary congestion" and "alveolar pneumonopathies."

The pattern of increasing death rates in states with the highest compared with lowest AIDS incidence was not observed for the other cause-of-death groups we examined. To determine whether causes of death not recognized using these categories had such a pattern, we further reviewed numbers of deaths in 1980 and 1986 using ICD-9 codes at the major subheading level (e.g., the first three digits of the four-digit ICD-9 codes), after excluding conditions which accounted for <25 deaths in the two years combined. This review did not identify additional underlying causes with this pattern, with the possible exception of diabetes mellitus, which increased slightly from 2.2/100,000 in 1980 to 2.9/100,000 in 1987 in the highest AIDS incidence states, while remaining stable during this period in the lowest AIDS incidence states.

Race-specific Trends

For both White and Black men, lowest overall death rates for the 25–44 year age group were in 1983. For White men, death rates declined from 204.8/100,000 in 1980 to 187.3/100,000 in 1983, then rose 9 percent to 204.1/100,000 in 1987. For Black men, death rates declined from 510.3/100,000 in 1980 to 431.6 in 1983, then rose 19 percent to 513.5/100,000 in 1987. In 1987, death rates for HIV/AIDS and conditions in the AIDS definition for men in this age group were 22.2/100,000 for

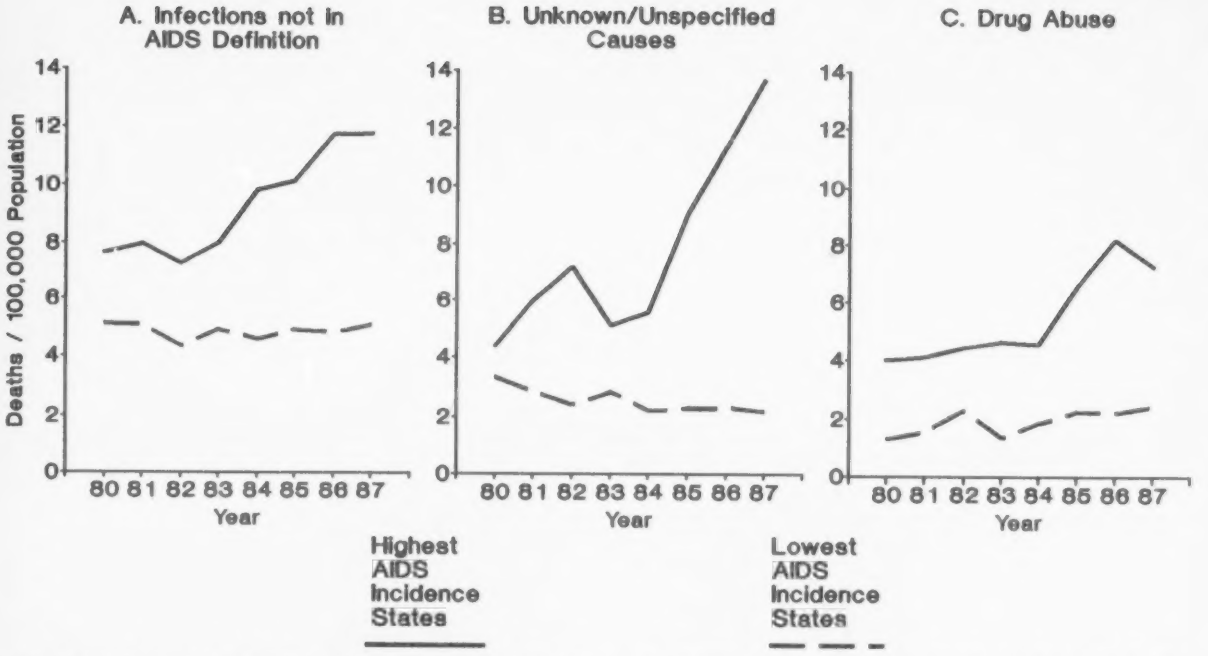

FIGURE 2—Death Rates per 100,000 Population, Men 25–44 Years of Age, Deaths due to Selected Causes with Rates that Diverged from 1980 to 1987 in the Highest Compared with Lowest AIDS Incidence States, United States, 1980–87

White men and 67.1/100,000 for Black men. For infections not in the AIDS definition, death rates increased from 4.2/100,000 in 1980 to 5.3/100,000 in 1987 for White men, and from 20.7 to 26.1/100,000, respectively, for Black men.

Estimate of HIV-related Deaths

In 1987, the estimate of HIV-related deaths in men 25–44 years of age ranged from 10,290 to 13,350, based on the number of excess deaths for those causes identified above as increasing in association with the HIV epidemic (Table 3). The model used for calculating excess deaths is illustrated in Figure 3 for pneumonia and influenza. The minimum estimate of HIV-related deaths (10,290 deaths) represents the number with mention of HIV/AIDS on death certificates and excess deaths due to conditions in the AIDS definition (Table 3). An intermediate estimate of HIV-related deaths, adding those due to infections not in the AIDS definition and other immune defects, is 11,470. The maximum estimate (13,350) includes excess deaths for all causes increasing in association with the epidemic. The 9,838 deaths with certificates that mentioned HIV/AIDS on multiple-cause listings represented 74–96 percent of estimated HIV-related deaths. This compares to 9,430 deaths occurring in 1987 among men 25–44 years of age and reported to national AIDS surveillance through December 1989, representing 71–92 percent of estimated HIV-related deaths for men in this age group.

In the absence of deaths due to HIV/AIDS and excess deaths due to these associated causes, the death rate in 1987 for men 25–44 years of age would have been 201 to 209/100,000, a decline of 11–15 percent from 1980 using the range of estimates of HIV-related deaths. Instead, death rates showed no net decline from 1980 to 1987.

TABLE 3—Estimate of HIV-related Deaths Men 25–44 Years of Age, United States, 1987

	Number of Deaths	Cumulative Total[a]
HIV/AIDS listed on death certificate	9,838	
HIV/AIDS not listed on death certificate, excess deaths with underlying cause[a]

[f]Excludes infections.

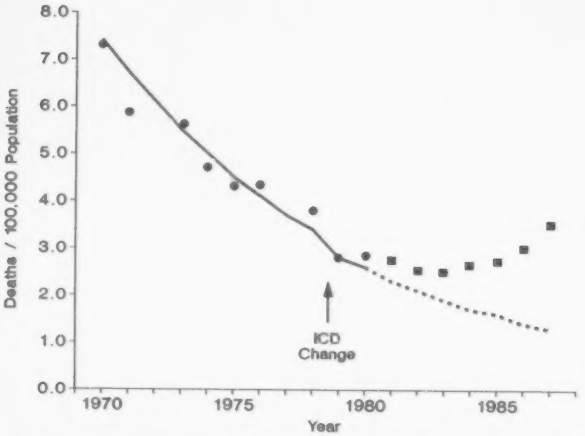

FIGURE 3—Death Rates per 100,000 for Pneumonia and Influenza, Men 25–44 Years of Age, United States, 1970–87
Circles represent observed rates for 1970–80. Squares represent observed rates for 1981–87 (excluding deaths with diagnoses coded as "deficiency of cell-mediated immunity, *Pneumocystis carinii* pneumonia or Kaposi's sarcoma in 1980–86 or as HIV/AIDS in 1987). Solid line represents baseline for rates in 1970–80 and dashed lines predicted rates for 1981–87.

Discussion

The HIV/AIDS epidemic has led to an increase in death rates for young men in the United States. Our findings are similar to those in England and Wales, where death rates have also recently increased in young men, primarily because of causes associated with HIV.[25] By 1987, deaths due to HIV/AIDS and conditions in the surveillance definition for AIDS accounted for more than 10 percent of deaths among men 25–44 years of age. Among Black men, death rates for these conditions were three times the rates for White men in 1987, reflecting disparities in AIDS incidence.[26] In addition, by comparing cause-specific mortality trends in states with high versus low incidence of AIDS, we have identified other causes of death that are increasing in association with the HIV epidemic.

Most notable is an increase in deaths due to infections that are not part of the surveillance definition for AIDS, such as pneumonia, septicemia, and pulmonary tuberculosis. This is consistent with clinical and epidemiologic observations that persons with HIV-related immune dysfunction are susceptible to a broad spectrum of infectious complications in addition to the "opportunistic" infections included in the AIDS surveillance definition.[27] Increases in morbidity and mortality due to these conditions have been noted most prominently in association with intravenous drug use,[28–31] although the risk of severe bacterial infections among HIV-infected persons is not limited to intravenous drug users.[32] The increase in deaths due to pulmonary tuberculosis is consistent with increases in tuberculosis noted in association with HIV and AIDS.[33–37]

The observation that deaths due to blood disorders such as agranulocytosis, thrombocytopenia, and unspecified coagulation defects increased in states with the highest AIDS incidence is consistent with recognized hematologic complications of HIV infection.[38] The finding that immune deficiencies other than cell-mediated immune deficiency (ICD-9 No. 279.1) are increasing is not surprising, given the spectrum of immune defects caused by HIV infection[39] and possible variations in the reporting and coding of HIV-related immune deficiencies.

The divergence in trends for deaths due to drug abuse in states with the high and low AIDS incidence probably reflects differences in both levels of illicit drug use and HIV infection among drug users, particularly in New York and New Jersey.[40] We cannot discern, however, to what extent the upward trend in death rates for drug abuse reflects trends in illicit drug use independent of the HIV epidemic. This possibility was considered but discounted by Stoneburner, *et al*, who studied mortality trends in New York City. While deaths in narcotic users increased from 1979 to 1986, overdose deaths did not increase, which should have occurred if narcotic use had increased.[28]

Similarly, for all causes that are increasing in association with the HIV epidemic, it is not possible to measure by death certificates alone what proportion of the increase is attributable to HIV infection. In some cases HIV infection may be unrecognized, and in others physicians may be unwilling to specify AIDS or HIV on death certificates. For example, the increase in deaths classified as due to "pneumonia" or non-infectious respiratory conditions may reflect the use of euphemisms for AIDS or *Pneumocystis carinii* pneumonia, or the lack of a full diagnostic evaluation. Likewise, the marked increase in deaths with unspecified cause in highest AIDS incidence states may reflect a failure to diagnose HIV infection or, alternatively, incomplete postmortem testing at the time of death certificate coding. Conversely, the categories we used for AIDS indicator diseases may capture some deaths that are unrelated to HIV infection. In 1980, over 500 deaths were due to conditions in the AIDS definition. While a few of these deaths may have been due to HIV infection, the majority most likely reflect the background occurrence of these conditions.

In addition to cancers in the AIDS definition, other cancers have had a suggested link to HIV infection.[11–19] We examined trends in deaths due to several of these cancers (Hodgkin's lymphoma, oral-pharyngeal cancer, anal-rectal cancer) but did not observe an increase in death rates or a divergence in trends for states with high and low AIDS incidence. This does not exclude an etiologic link between HIV and these conditions but suggests that if there is a link, it has not had a substantial effect on mortality trends. Similarly, population-based studies have not found statistically significant increases in the incidence of Hodgkin's lymphoma when high and low AIDS incidence areas were compared or when trends were examined for married and unmarried men.[41–44]

Increased rates of suicide among men with AIDS compared to other men have been described in New York and California.[45,46] Nationally, we observed that suicide and HIV/AIDS were listed together for 33 deaths in 1987, but we did not observe a difference in suicide trends for states with a high versus low AIDS incidence. This suggests that suicides among men with HIV infection has not had a substantial effect on suicide trends.

We have estimated that up to 13,350 HIV-related deaths occurred in 1987 among men 25–44 years of age, based on the number of deaths with HIV/AIDS listed on death certificates and on excess deaths for conditions that are increasing in association with the HIV epidemic. This estimate should be considered approximate for several reasons. We assumed that mortality trends during the 1970s would have continued unchanged during the 1980s in the absence of the HIV epidemic; for some causes we were unable to define a baseline trend in the 1970s; and some HIV-related deaths may be attributed to causes not included in our estimate.

New codes introduced in 1987 improve the classification of HIV-related deaths in national vital statistics. Nonetheless, our findings indicate that death certificates listing HIV/AIDS do not describe the full extent of HIV-related mortality. Similarly, our estimate of HIV-related deaths exceeds the number of deaths reported through national AIDS surveillance. Underreporting will affect both systems if HIV/AIDS is not diagnosed or if physicians are unwilling to report the diagnosis to health agencies. Also, HIV/AIDS may not be listed on death certificates in instances where physicians judge the cause of death to be unrelated to HIV infection. AIDS surveillance undercounts HIV-related deaths to the extent that AIDS cases and subsequent deaths are underreported and that persons with HIV-related disease do not meet surveillance criteria for AIDS. Thus, our estimate that 70–90 percent of HIV-related deaths in 1987 among men 25–44 years of age were detected by AIDS surveillance (which is somewhat higher than a comparable estimate for England and Wales[47]) indicates that reporting for those with disease meeting surveillance criteria must be at least this complete.

The concept of surveillance is increasingly being expanded beyond case reporting to encompass analyses of other data resources, such as vital statistics.[48] Comparison of mortality trends in areas with varying AIDS incidence provides a useful complement to AIDS surveillance in describing both the spectrum of conditions associated with HIV infection and the impact of the HIV epidemic on mortality trends.

ACKNOWLEDGMENTS

The authors thank John Anderson, PhD, for his assistance in using state-level population estimates, John M. Karon, PhD, and Robert H. Byers, PhD, for their assistance in conducting the analyses, and James W. Curran, MD, MPH, and Harry M Rosenberg, PhD, for their suggestions. These data were presented in part at the V International Conference on AIDS, Montreal, Canada, June 4–9, 1989.

AAA Pedestrian Protection Program Names Four Safest Communities in 1989

The American Automobile Association recently released the results of its 51st annual Pedestrian Protection Program which recognizes communities and states that have made outstanding achievement in pedestrian safety. The four locations in America judged to be the safest places to be a pedestrian are: the State of Wisconsin; Henrico County, Virginia; San Jose, California; and Rocklin, California. According to Bill Bowes, AAA manager of community programs, "these communities have made strong efforts in traffic safety programs, including education at all levels of their population. They work hard at making sure their streets are safe."

The AAA Pedestrian Protection Program is designed to encourage cities and states to teach pedestrian safety and to strictly enforce related laws. Communities also work with AAA to improve their programs. The participating cities are grouped by population size and graded on safety programs, enforcement levels, traffic engineering, pedestrian deaths, and injury rates.

San Jose had a pedestrian death rate of 2.3 per 100,000 population and an injury rate of 54/100,000 in 1989. Comparable rates for the other winners were: Wisconsin, 1.4 deaths and 43 injuries/100,000; Henrico County, 1.9 deaths and 17 injuries/100,000; Rocklin, no deaths and 17 injuries/100,000.

Educational programs in schools and senior centers teach children, adults and senior citizens pedestrian safety. San Jose's active enforcement program led to 355 tickets issued to pedestrians crossing against traffic signals. Most pedestrians killed in the United States either violated traffic laws or behaved carelessly, AAA said. Since the Pedestrian Protection Program began in 1937, pedestrian fatalities have dropped from 15,500 per year to 8,800 in 1989. AAA also distributed a fact sheet about pedestrians, which included the following:

- The first recorded traffic fatality in the US occurred in 1899 in New York City. The victim was a pedestrian.
- The economic loss from pedestrian accidents in the US is estimated at more than $1 billion annually.
- At least 90 percent of all children injured enroute to or from school were struck where no type of special school crossing protection (safety patrols, adult guards, police officers) was in use.
- Pedestrians under age 15 and over age 64 account for 41 percent of all pedestrian fatalities; 17 percent of pedestrian deaths and 37 percent of pedestrian injuries are to those under age 15; older adults account for 24 percent of pedestrian deaths and 10 percent of pedestrian injuries.
- Pedestrian deaths are three-fold greater than combined air, marine and rail transport deaths.

Premarital Screening for Antibodies to Human Immunodeficiency Virus Type 1 in the United States

LYLE R. PETERSEN, MD, CAROL R. WHITE, MT, AND THE PREMARITAL SCREENING STUDY GROUP*

Abstract: To evaluate premarital human immunodeficiency virus (HIV) screening as an approach to AIDS prevention in the United States, we determined the HIV antibody seroprevalence in marriage license applicants in eight areas by blinded testing of blood specimens routinely collected for syphilis serology. The seroprevalences were 0.0–0.4 percent in women and 0.0–1.1 percent in men. We also examined the impact of mandatory premarital HIV screening on marriage rates in Louisiana and Illinois. In 1988, after screening began, 9 percent and 16 percent fewer marriage licenses than in the previous two years were issued in Louisiana and Illinois, respectively. We estimated that mandatory premarital screening, if adopted nationally, would cost $167,230,000. We conclude that compared with other HIV prevention programs mandatory premarital screening would be expensive and would probably have a minor impact on the HIV epidemic. (*Am J Public Health* 1990; 80:1087–1090.)

Introduction

Mandatory premarital screening for human immunodeficiency virus type 1 (HIV-1) antibodies, a measure proposed to reduce heterosexual and perinatal transmission of HIV infection, would require testing of 2.4 million couples annually if adopted in every state.[1] Arguments for and against mandatory screening focus on public health, scientific, ethical, political, and financial considerations.[2–4] A recent analysis arguing that premarital screening would not be cost effective was based on HIV seroprevalence rates among blood donors because rates in marriage license applicants were unknown.[2] However, HIV seroprevalence may be lower in blood donors than in marriage license applicants because these two groups are demographically dissimilar[5,6] and persons at risk for HIV infection are actively discouraged from donating blood.[7]

To evaluate the use of premarital HIV screening as an approach to HIV prevention, we determined the HIV antibody seroprevalence in marriage license applicants in eight areas. In addition, we examined the impact of mandatory premarital screening on the number of marriages in Louisiana and Illinois.

Methods

Premarital syphilis and/or rubella serologic testing is required in 20 states. From November 1985 to December 1988, we conducted blinded (test results unlinked to personal identifiers) HIV seroprevalence studies using blood specimens submitted to local or state health department laboratories for mandatory premarital syphilis screening in Alabama, California (Alameda County and City of Long Beach only), Connecticut, Georgia, Mississippi, New Mexico (Bernalillo County only), and Oklahoma. Areas for the blinded surveys were chosen on the basis of availability of specimens and desire by local or state health officials for a blinded survey. In each blinded survey, excess sera were tested for HIV antibody after the routine syphilis serologic testing was performed and personal identifiers were removed. In some locations, limited demographic data were available. No sera were collected specifically for HIV antibody testing. In Alameda County, specimens were submitted by seven public health clinics; in the other locations, by private physicians, public health clinics, the Indian Health Service, and hospital laboratories. In California, marriage license applicants who had been living together for ≥6 months could choose an option (23 percent of applicants in 1987) not requiring syphilis testing.

For each blinded survey location, comparison HIV seroprevalence data were obtained from the US Department of Defense military applicant screening program[8,9] and adjusted to the national age and gender distribution of marriage license recipients reported to the National Center for Health Statistics (NCHS).[5] The cumulative incidences of acquired immunodeficiency syndrome (AIDS) in adults (≥13 years of age) from 1978 to 1988 were computed from surveillance data from the Centers for Disease Control (CDC) and population denominators from the 1980 census.

Louisiana and Illinois began mandatory premarital HIV screening on January 1, 1988. Because only positive results were reported to the Illinois Department of Public Health, statewide seroprevalence rates in applicants could only be estimated by comparing the number of reported seropositive applicants to the total number of marriage licenses issued in Illinois during 1988. A description of the Illinois program has recently been published.[10] HIV antibody test results were not reported in Louisiana. Although statewide seroprevalence in applicants could not be directly measured in either state, seroprevalence information was obtained from six blood centers within these states that offered HIV antibody testing as a service to marriage license applicants.

The impact of the Illinois and Louisiana mandatory screening laws on marriage rates was evaluated using final data on the annual number of marriages from 1980 to 1985[11] and provisional NCHS data from 1986 through 1988 for 49 states and the District of Columbia.[12]

The potential cost of premarital HIV screening, if adopted nationally, was based on the estimated 2,389,000 couples who married in 1988.[12] Based on the fact that observed premarital applicant HIV prevalence rates were more similar to those of military applicants than to those of other national population groups tested for HIV (e.g., blood donors), we assumed that the national HIV seroprevalence rates in marriage license applicants were equal to national rates for military applicants age-adjusted to marriage license recipients (0.31 percent men, 0.10 percent women). We assumed the average cost of HIV testing and counseling would be $35. This cost was similar to overall cost estimates used by others[2,10] and slightly lower than the average cost of HIV counseling and testing in public sites funded by the CDC ($42 for seronegative and $92 for seropositive persons). The sensitivity and specificity of sequential EIA and Western blot were assumed to be 99.0 percent and 99.999 percent, respectively. The specificity of 99.999 percent was used because the false-positive rate of the sequential enzyme immunosorbent assays (EIA) and Western blot has been shown to be less than 1 in 100,000 under optimal quality assurance conditions.[13,14]

Specimens from the blinded surveys and the HIV screening performed at blood centers in Louisiana and Illinois were tested for HIV antibody by licensed EIA. Repeatedly reactive specimens from the Alameda County and Long Beach Health Departments were confirmed by immunofluorescence assay (IFA), and repeatedly reactive specimens obtained elsewhere were confirmed by Western blot. Specimens confirmed by Western blot were considered positive at the Tulane Blood Center and at the American Red Cross Blood Services Heart of Illinois Region (Peoria, IL) if p24, p31 and either gp41 or gp160 bands were present. At the other centers, at least two of the following three bands were required: p24, gp41, and gp 120/160. These two criteria have been shown to yield similar results in asymptomatic persons.[15]

Results

Blinded Premarital HIV Seroprevalence Studies

Seroprevalences were from 0 to 0.7 percent (Table 1). Gender-specific marriage license applicant HIV antibody prevalences were 0–0.4 percent for women and 0–1.1 percent for men. Data from New Mexico, Oklahoma, Connecticut, and Georgia indicated HIV seroprevalence may be highest in persons 20 to 39 years of age (Table 2). The observed HIV antibody prevalence in Black marriage license applicants was higher than that of non-Hispanic White applicants in Georgia (Table 3). Race-specific data were not gathered in other states except Oklahoma where the number of non-Whites was small.

States with Mandatory Premarital Testing

In Illinois, 16 percent fewer marriage licenses were issued in 1988 than the average in 1986 and 1987, the two years before mandatory premarital screening was instituted (Table 4). Correspondingly, the number of marriages increased by 7 percent in states surrounding Illinois (Table 4). In Louisiana, there were 9 percent fewer marriages in 1988 than in 1986 and 1987—similar to the 7 percent decrease in its surrounding states (Table 4). The decrease in Louisiana only occurred during the period of screening, however. Compared to similar periods in the two preceding years, the number of marriage licenses issued in Louisiana decreased by 19 percent from January to June when the law was in effect, but from July to December the number remained at levels similar to those of the two preceding years (+0.5 percent). In contrast, the number of marriages decreased during the first (−18 percent) and second (−14 percent) halves of 1988 in Illinois where the law was in effect for the entire year. The decrease in marriages in states bordering Louisiana was due entirely to a decrease in marriages in Texas, a state with a population nearly four times that of Louisiana.

In Illinois, a total of 80,490 marriage licenses were issued in 1988; 26 persons (0.02 percent of 160,980 persons) with

§Mississippi (+5 percent), Arkansas (+11 percent), Texas (−11 percent).

positive HIV antibody tests were reported. It is unknown how many of these seropositive persons were pairs.

Seroprevalences from six blood centers with HIV antibody screening services for premarital applicants in Louisiana and Illinois were 0.0 percent to 0.9 percent (Table 5). Nine of the 10 seropositive marriage license applicants identified from the six blood centers had partners who were also tested at the blood centers; all were seronegative.

National Premarital Screening Projections

A total of 9,795 persons (7,406 males and 2,389 females) of the 2,389,000 couples marrying would have HIV antibody if the seroprevalence in that population were the same as that for military applicants. At $35 per person screened, the cost would be $167,230,000. If the overall sensitivity and specificity of HIV testing were 99.0 percent and 99.999 percent, 9,697 persons (7,332 men and 2,365 women) would be correctly identified as seropositive at a cost of $17,246 per seropositive person detected. The overall predictive value positive of the sequential EIA and Western blot would be 99.5 percent under optimal quality assurance conditions. There would be 48 persons with false-positive test results.

Discussion

Observed marriage license applicant HIV seroprevalences varied considerably—from less than 0.1 percent in two states to 0.66 percent in Alameda County, California—and areas with high HIV antibody prevalences generally had the highest cumulative AIDS incidences. These data suggest that the national HIV seroprevalence in marriage license applicants is of the same order of magnitude of that in military applicants (0.21 percent [adjusted to the age and gender distribution of marriage license recipients]) than to that in blood donors (0.012 percent).[16] Our data should be interpreted with caution, however, as there were few marriage license applicants in some study locations, these locations were not randomly chosen, and the effect of selection biases could not be fully determined.

Our data from the blinded seroprevalence studies of specimens collected for routine premarital syphilis screening suggest that the seroprevalence in marriage license applicants was much higher than that indicated by our data and those of Turnock and Kelly[10] gathered from reporting of seropositive persons identified by mandatory screening in Illinois. The calculated seroprevalence (<0.02 percent) based on reporting in Illinois was half that found in the blinded study in Oklahoma, a state with a lower cumulative incidence of AIDS in adults (128 vs 203 per million adult population) and a lower HIV prevalence in military applicants (0.09 percent vs 0.24 percent). In addition, although the numbers of premarital applicants tested in the two Illinois blood banks reported here were relatively few, the observed seroprevalences were higher than the calculated statewide seroprevalence despite the fact that these two blood banks were located in relatively low AIDS incidence areas. These discrepancies could have been due to underreporting of seropositive persons to the Illinois Department of Public Health; moreover, persons who knew they were infected or were at increased risk for HIV infection might have deferred marriage or traveled to adjacent states to marry.

Marriage rates decreased in Louisiana and Illinois after the mandatory screening laws took effect. Although we could not determine what proportion of this decrease was due to HIV screening, in Louisiana, the decrease in marriages occurred only in the first half of 1988 when the screening requirements were in effect. In Illinois, the number of marriages increased in adjacent states, and others have shown that some of this increase was due to border crossing

by Illinois residents to avoid screening.[10,17] These data suggest that the efficacy of mandatory screening in identifying seropositive persons may be less than expected, especially if alternatives exist, such as marrying in adjacent states.

Premarital HIV screening would undoubtedly have little overall effect on heterosexual and perinatal transmission because most unmarried adults are sexually active[18] (only 63 percent of first births in the United States are conceived within marriage)[19] a negative premarital antibody test does not guarantee that a person will remain seronegative throughout the duration of the marriage; some persons counseled after a positive antibody test may not change their sexual or childbearing behavior to negate the risk of future HIV transmission; and groups with high seroprevalence may be less likely to marry before heterosexual or perinatal transmission occurs. For example, in New York State, the HIV seroprevalence in Black childbearing women is over 10 times that of White women,[20] and national figures indicate that 74 percent of first births to Black women are nonmaritally conceived compared to 31 percent in White women.[19] Data suggest that 75 percent of children with perinatally acquired AIDS in New York City are born to unmarried women.[2] Therefore, premarital HIV screening cannot be considered a substitute for other public health strategies to reduce perinatal and heterosexual HIV transmission.

The cost of mandatory HIV screening, if adopted nationally, is likely to be high relative to other HIV prevention programs. We estimated the cost to be $167,230,000, nearly 80 percent as high as the $211,889,000 Congressional appropriation to CDC for all public health HIV control measures for fiscal year 1988. The average cost of identifying a seropositive person was estimated to be $17,246, compared to approximately $925 in public sites funded by CDC (unpublished data). The actual cost of identifying a seropositive person may be much higher than we estimated because persons at high risk for HIV infection may decline to marry or may travel to adjacent states to avoid the screening requirements. In Illinois, the actual cost was estimated to be $312,000 per seropositive person during the first six months of screening.[10] Although the cost of mandatory screening could be borne by marriage license applicants, the poor—likely to be at higher risk for HIV infection—may avoid screening because of the cost.[10] The benefit of mandatory premarital HIV screening on HIV prevention is unknown.

Alternative strategies for preventing heterosexual and perinatal HIV transmission include increasing the availability of drug treatment for intravenous drug users (IVDUs) and HIV counseling and testing of clients in drug treatment centers and of all pregnant women at increased risk for HIV infection.[21,22] In addition, several states have adopted voluntary HIV screening for marriage license applicants.[23] Marriage license applicants are required to receive information about HIV infection, risk behavior, measures to avoid transmission of HIV, and availability of HIV testing and counseling. The efficacy of this approach is unknown.

We conclude that the high cost of mandatory premarital screening relative to other public health programs, its uncertain efficacy in identifying seropositive persons and preventing heterosexual or perinatal HIV infection, and the fact that persons will travel to adjacent states to avoid screening do not appear to justify its institution.

ACKNOWLEDGEMENTS

We thank Julie A. Darling, MT, Cynthia A. Eicher, MT, and Bernard J. Turnock, MD, for providing data for the manuscript, and John Anderson, PhD, for analyzing census data and military applicant HIV seroprevalences.

Hepatitis Transmission among the Sioux Indians of South Dakota

FREDERIC E. SHAW, JR., MD, CRAIG N. SHAPIRO, MD, THOMAS K. WELTY, MD, MPH, WILLIAM DILL, PHD, JAY REDDINGTON, MD, AND STEPHEN C. HADLER, MD

Abstract: Hepatitis A continues to occur in cyclical community-wide epidemics on the Indian reservations of South Dakota. In June 1985 a population-based serosurvey for viral hepatitis involving 120 households was conducted at the Pine Ridge and Rosebud Sioux Indian reservations in South Dakota. The serosurvey was performed shortly after a large hepatitis A epidemic on the Pine Ridge reservation in 1983–84, and immediately before a large hepatitis A epidemic on the Rosebud reservation in 1985–86. The overall seroprevalence for antibodies to hepatitis A virus (anti-HAV) was 76.2 percent (Pine Ridge reservation 80.5 percent, Rosebud reservation 72.0 percent, relative risk = 1.12, 95 percent confidence interval = 1.01, 1.24). For age groups 0 to 4 years, 54.2 percent and 36.1 percent of children were seropositive at Pine Ridge and Rosebud, respectively. Seropositivity rose rapidly with age; by age 40, more than 90 percent of persons at both Pine Ridge and Rosebud were anti-HAV positive. Only 1.1 percent of persons tested were positive for hepatitis B markers. Anti-HAV seroprevalence rates in both communities are similar to rates observed in developing countries. The surprisingly high anti-HAV seroprevalence among young children at Rosebud, where clinical hepatitis A had been virtually absent in the previous seven years, indicates that high-grade silent transmission was taking place during the interepidemic period. (*Am J Public Health* 1990; 80:1091–1094.)

Introduction

Hepatitis A is endemic among most Native American tribes in North America. Rates of hepatitis A in Native Americans in the United States are four to five times higher than national rates in recent years (Centers for Disease Control, unpublished data). Outbreaks of hepatitis A have been a problem on reservations of South Dakota for many years. In the past several decades, they have occurred regularly, usually in cyclical patterns. Typically, outbreaks appear every 7 to 10 years, each one lasting 6 to 24 months. Frequently, the outbreak cycle on one reservation does not coincide with the cycle on nearby reservations. Sometimes a large outbreak occurs at one reservation while a nearby reservation is quiescent.

Such a situation existed in 1985 at two adjacent Sioux reservations in South Dakota, Pine Ridge and Rosebud. At Pine Ridge, an outbreak of hepatitis A began in early 1983 and continued into 1984. It became quite large, eventually involving several hundred people. During the same time, the Rosebud reservation was in an interepidemic period. In late 1985, a large outbreak began at Rosebud and continued into 1986. A cross-sectional seroprevalence survey for viral hepatitis was conducted at the two reservations in June 1985, after the Pine Ridge outbreak but before the Rosebud outbreak. The results allow comparison of the hepatitis serologic profiles of a reservation in a postepidemic period with a reservation in an interepidemic period.

Methods

The Pine Ridge and Rosebud reservations lie in the rolling prairie hills of South Dakota, at the state's southern border with Nebraska. The 1985 population of Pine Ridge was 16,020; the population of Rosebud reservation was 8,473. The two reservations are divided into small villages, nine at Pine Ridge and 20 at Rosebud. The counties that make up the reservations are among the poorest in the United States as determined by per capita income. There is moderate interaction between the two communities, with occasional shared social events. Children from each reservation attend different schools. Due to the long time presence of Indian Health Service Hospitals, public health nurses, and local community health representatives, the level of hepatitis case reporting has been relatively complete at both reservations.

Epidemic Data

The data sources for hepatitis A incidence rates over two decades and for the epidemic curves of the Pine Ridge and Rosebud outbreaks were from notifiable disease reports collected by the South Dakota State Health Department. Only cases from the three largest counties in each reservation (Pine Ridge—Shannon, Jackson, Bennett counties; Rosebud—Todd, Mellette, Tripp counties) were included. Incidence rates and age-specific attack rates were calculated using 1980 US census data and intercensal population estimates.

Hepatitis Seroprevalence Survey

The geographical study area was defined as the largest villages on each reservation that together represented 75 percent of the population of each reservation: at Pine Ridge, four villages (Kyle, Oglala, Pine Ridge, and Wanblee), at Rosebud, 12 villages (Antelope, Black Pipe, Corn Creek, He Dog, Horse Creek, Parmalee, Ring Thunder, Rosebud, St. Francis, Soldier Creek, Swift Bear, and Upper Cut Meat). Using maps of each village divided into block areas, housing units were selected for study by simple random geographic sampling, 70 at each reservation. Empty or unoccupied houses were replaced with the next sequential house. Three visits to each house were made before it was classified as a refusal; refusals were not replaced. Each household selected was visited by a study team consisting of a primary investigator and a local nurse or community health representative. After obtaining consent, a questionnaire was administered to the household head asking about the age, sex, race, and clinical history of hepatitis of each household member. In addition, household characteristics were ascertained, including the number of rooms and the presence of indoor or outdoor water supply and toilet facilities. Blood specimens

From the Hepatitis Branch, Division of Viral and Rickettsial Diseases, Center for Infectious Diseases, Centers for Disease Control, Atlanta, GA (Drs. Shaw, Shapiro, Reddington, and Hadler); the Aberdeen Area Indian Health Service, Public Health Service Indian Hospital, Rapid City, SD (Dr. Welty); and the Aberdeen Area Indian Health Service, Aberdeen, SD (Dr. Dill). Address reprint requests to Craig N. Shapiro, MD, Hepatitis Branch, Division of Viral and Rickettsial Diseases, Center for Infectious Diseases, CDC, Building 6, Room 154, Atlanta, GA 30333.

were obtained from all household members one year of age or older.

Laboratory Assays

Tests for immunoglobulin M antibody to hepatitis A virus (IgM anti-HAV) and total antibody to hepatitis A virus (anti-HAV) were performed by using commercially available enzyme immunoassays; tests for hepatitis B surface antigen (HBsAg), antibody to hepatitis B core antigen (anti-HBc), and antibody to hepatitis B surface antigen (anti-HBs) were performed by using commercially available radioimmunoassays (Abbott Laboratories, North Chicago, Illinois).

Statistical Analyses

Confidence limits for relative risk estimates were calculated using the formulas of Greenland and Robins.[1]

Results

Data from Recent Outbreaks

Hepatitis A has occurred cyclically for many years on Pine Ridge and Rosebud reservations (Figure 1). The epidemic curves of hepatitis A outbreaks on Pine Ridge and Rosebud reservations in 1983–86 are shown in Figure 2. Transmission was predominantly person-to-person. There was no evidence for a common source. The age-specific attack rates for the two outbreaks show that the age distribution of patients at Pine Ridge and Rosebud were very similar and that the highest rates of disease were for younger groups aged 5 to 9 years (Table 1).

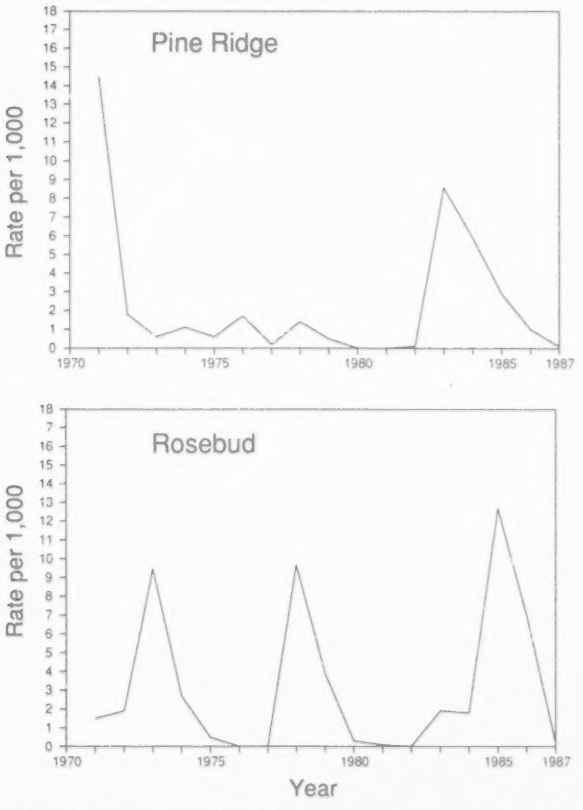

FIGURE 1—Hepatitis A Rates (per 1,000 population), Pine Ridge and Rosebud Reservations, South Dakota, 1971–87

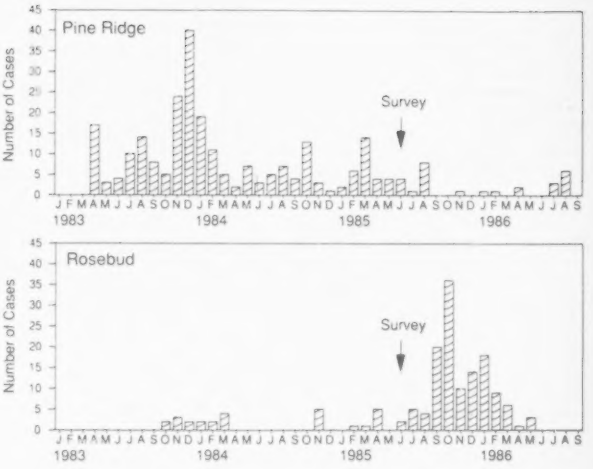

FIGURE 2—Hepatitis A Cases, by Report Date, Pine Ridge and Rosebud Reservations, South Dakota, January 1983 to September 1986

Hepatitis Seroprevalence Survey

Demographic Variables—The enrolled households numbered 120: 60 at Pine Ridge Reservation and 60 at Rosebud Reservation. A total of 605 persons lived in these households (Pine Ridge, 297; Rosebud, 308), for a mean of five persons per household (range, 1 to 16). The percentage of persons younger than 20 years of age who were in the study group did not differ substantially from the percentage in the 1980 census for the reservation areas (56.4 percent vs 53.1 percent, respectively), nor did the percentage of residents who were males (47.1 percent vs 49.7 percent, respectively).

Of the 605 persons, 590 were one year of age or older. Blood specimens from 467 persons were obtained and tested for hepatitis serologic markers. Demographic characteristics of the persons interviewed and tested are shown in Table 2. Characteristics of persons tested did not differ significantly from all household members identified.

Of the households visited, 93 percent had running water and 89 percent had flush toilets. The mean number of rooms per house was five.

*Relative risk, 95 percent confidence interval, within each category

Serologic Results—At both reservations combined, 76.2 percent (356/467) of persons tested were positive for anti-HAV. The prevalence rate at Pine Ridge was slightly higher than at Rosebud (80.5 percent vs 72.0 percent, relative risk [RR] = 1.12, 95 percent CI = 1.01, 1.24). Seropositivity rates of individual villages within each reservation were roughly comparable (Table 3). Rates in males were not significantly different from rates in females at either Pine Ridge (82.2 percent males vs 79.0 percent females, RR = 1.04, 95 percent CI = 0.92, 1.18) or Rosebud (73.8 percent males vs 70.5 percent females, RR = 1.05, 95 percent CI = 0.89, 1.23). Of the 11 Whites tested, seven (63.6 percent) were positive, compared with 349 (76.5 percent) of 456 Native Americans. Of the 356 persons positive for anti-HAV, 10 (2.8 percent) were also positive for IgM anti-HAV, indicating recent infection. Of these persons, seven were from Pine Ridge, and three were from Rosebud; the range of ages was two to 41 years (median 7.5 years).

Anti-HAV seropositivity was strongly associated with age (Figure 3). At Pine Ridge and Rosebud reservations, respectively, 54.2 percent and 36.1 percent of children aged 0–4 years were anti-HAV positive (RR = 1.50, 95 percent CI = 0.84, 2.68). Prevalence rates at both reservations rose rapidly with increasing age, although more rapidly at Pine Ridge. By age 15, over 90 percent of persons at Pine Ridge were anti-HAV positive; rates did not reach 90 percent until age 30 years at Rosebud. In young adults ages 15–29, anti-HAV seropositivity was slightly higher at Pine Ridge than at Rosebud (91.1 percent vs 71.1 percent, RR = 1.28, 95 percent CI = 1.06, 1.54). Rates between reservations were not significantly different in adults ages 30 or more years (93.8 percent vs 91.6 percent, respectively, RR = 1.02, 95 percent CI = 0.94, 1.12).

Antelope	72.4 (21/29)
Total	72.0 (170/236)

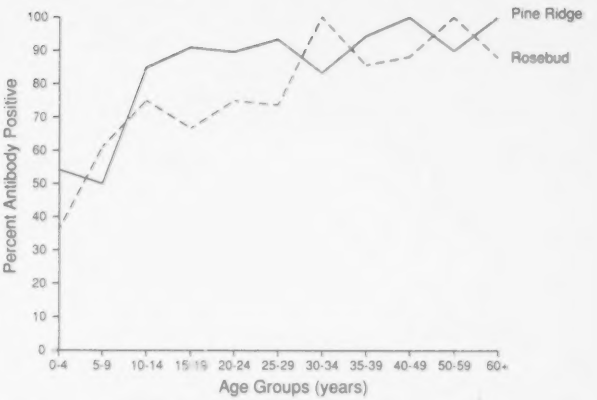

FIGURE 3—Anti-HAV Prevalence by Age Group, Pine Ridge and Rosebud Reservations, South Dakota, June 1985

Other personal characteristics which were examined included having been born on Pine Ridge or Rosebud reservation or having a history of hepatitis (Table 2). Persons born on one of the reservations were more likely to be anti-HAV-positive (82.3 percent vs 69.4 percent). Persons with a history of clinical hepatitis were also more likely to be anti-HAV-positive; this was true for persons at both Pine Ridge (RR = 1.30, 95 percent CI = 1.01, 1.68) and Rosebud (RR = 1.42, 95 percent CI = 1.07, 1.90).

Only five persons were positive for hepatitis B markers: four were immune (anti-HBc and anti-HBs positive) and one was HBsAg positive. Two persons were members of the same family—a 13-year-old boy who was HBsAg-positive, and his mother who was anti-HBs positive. The mother had acute hepatitis 13 years previously, while living off the reservation, during the third trimester of her pregnancy.

Discussion

The seroprevalence results presented here show that hepatitis A is widespread in the Pine Ridge and Rosebud reservation populations. In age groups over 30 years, 80 to 100 percent of persons have anti-HAV antibodies, indicating previous infection. These seroprevalence rates are much higher than those observed in the general U.S. population and in blood donors, in whom rates among adults are generally below 50 percent.[2] High rates of hepatitis A infection among Native Americans are due in part to poor environmental conditions and conditions related to poverty on many reservations, including crowded living quarters, inadequate housing, poor sanitation, and lack of running water.

A striking finding of this study was the high anti-HAV seroprevalence rate in young children at the Rosebud reservation (36 percent of children ages 0 to 4 years) even though Rosebud was in an interepidemic period and the last epidemic

had occurred in 1978. These rates are very much higher than observed among children in other US settings,[3,4] and are comparable to rates in children in underdeveloped countries, where hepatitis A is endemic rather than epidemic.[5,6] Similar high hepatitis A seroprevalence rates among children in interepidemic periods have been observed among the Navajo in New Mexico.[7] In contrast, other studies in settings with cyclical epidemics suggest that transmission in interepidemic periods essentially ceases.[8,9] It appears that on these Indian reservations, at least, a significant amount of disease transmission occurs even in the absence of recognized epidemics, and the transmission is primarily among young children who have the lowest clinical/subclinical disease ratio.[10] Factors that cause this interepidemic transmission to lead to epidemic transmission are still poorly defined. A possibility is that transmission occurs constantly and silently, primarily among younger age groups, who serve as a reservoir for HAV infection; epidemic transmission may supervene periodically when a cohort of susceptible persons enlarges to a trigger level. An indication of this may be the somewhat lower anti-HAV antibody prevalence observed among children and young adults at Rosebud reservation, where an outbreak was about to occur, compared with Pine Ridge, where an outbreak had just occurred.

Another striking finding is the almost total lack of hepatitis B among Sioux Indians on Pine Ridge and Rosebud reservations. The only HBsAg-positive person, a 13-year-old boy, likely acquired the infection perinatally while his mother was living off the reservation. This lack of hepatitis B is consistent with low hepatitis B prevalence found among the Navajo and Hopi in northern Arizona.[11] In contrast, hepatitis B is endemic among Native Americans and Eskimos in Alaska.[12] It may be that behaviors or other factors that promote HBV transmission among Alaskan Eskimos are absent among Native Americans of the lower 48 states; alternatively, it may be that the hepatitis B virus (HBV) has never been introduced into the latter population.

Transmission of hepatitis A on reservations in the absence of outbreaks highlights the potential limitations of immune globulin (IG) as a control measure for hepatitis A in these settings. Furthermore, when community-wide outbreaks do occur, IG may not be effective in limiting the outbreaks unless it is given to the entire community simultaneously; this is rarely done because of impractical costs and logistics. Because IG does not confer immunity longer than about three months, in populations where hepatitis A occurs in large cyclical epidemics, mass use of IG might only delay the inevitable propagation to the whole susceptible community. Such a delay might result in a greater clinical disease burden; the inevitable infections might be shifted from young children, in whom infection is usually asymptomatic, to adults, in whom clinical illness is more likely.[13]

On Indian reservations, as well as in other parts of the United States, hepatitis A has significant human and economic impact, both in terms of morbidity and occasional mortality and in diverting of public health resources from other priorities when outbreaks occur. For the immediate future, outbreaks will probably continue to occur on the South Dakota and other Indian reservations. A safe, effective hepatitis A vaccine may be the only practical solution to control hepatitis A among Native Americans, and they are therefore a likely target population both for both vaccine testing and implementation. Several prototype vaccines have been developed, and are undergoing immunogenicity trials, with efficacy trials planned in the near future.[14–17] Until such a vaccine is available, conventional measures such as the promotion of handwashing, use of IG for household contacts of acute cases, and the improvement of general sanitation will remain important priorities.

Teaching Status and Resource Use for Patients with Acute Myocardial Infarction: A new look at the indirect costs of graduate medical education

I. Steven Udvarhelyi, MD, Terry Rosborough, MD, Richard P. Lofgren, MD, MPH, Nicole Lurie, MD, MSPH, and Arnold M. Epstein, MD, MA

Abstract: To investigate whether the process of graduate medical education increases costs in teaching hospitals by causing longer lengths of stay and greater resource use, we compared lengths of stay, hospital charges, and the use of cardiovascular procedures for patients with acute myocardial infarction admitted to the teaching and nonteaching services of a university-affiliated community hospital.

After adjusting for severity of illness and demographic characteristics, patients on the teaching services had a mean length of stay that was shorter by 0.6 days ($p = 0.04$) and mean charges that were $2,060 lower ($p = 0.15$) than for patients on the nonteaching service. Patients on the teaching service also had 15 percent (95% CI: −26, −4) fewer cardiac catheterizations and 9 percent (−18, 0) fewer procedures for myocardial revascularization (angioplasty or cardiac bypass surgery).

These findings suggest that graduate medical education per se may not directly increase the use of health care resources and that the cost differences between teaching and nonteaching hospitals may be largely a consequence of other factors. These factors may include epiphenomena of teaching such as a specialized organizational structure, specialized patient care services, and continuing medical education for the nursing and medical staffs. They may also include factors not related to teaching such as differences in patients' severity of illness and sociodemographic characteristics. (*Am J Public Health* 1990; 80:1095–1100.)

Introduction

Medicare is currently providing teaching hospitals with supplementary payments to compensate them for the indirect costs of graduate medical education. However, as the government focuses on controlling costs these payments have become controversial.[1] Other third party payers also are concerned about the contribution of graduate medical education to rising health care costs.[2] There is little question that teaching hospital costs are greater than those of nonteaching hospitals. It is commonly thought that a substantial portion of this difference in costs is attributable to the educational process engendering greater resource use, both in terms of longer lengths of stay and increased use of diagnostic and therapeutic services.[2–10] Implicit in the scrutiny of the indirect costs of graduate medical education is an assumption that they may represent inefficiency or waste in health care.

Despite the prevailing belief that graduate medical education increases the use of medical services, this view is not universally accepted.[11] The findings of previous studies of this issue may be questioned for at least two reasons:

- Most of them evaluated the costs of graduate medical education for patients cared for prior to the focus on cost containment which became prominent after the introduction of prospective payment for Medicare.[2–10] The traditional academic concern to "be complete" has probably been modified by growing interest in cost-effectiveness and efficiency during the 1980s.
- Second, some investigators argue that the indirect costs of graduate medical education are merely a consequence of differences in severity of illness between patients cared for in teaching and nonteaching hospitals.[12–15] Even authors who argue that severity of illness does not account for the cost differential between teaching and nonteaching hospitals acknowledge that adjusting for severity of illness and/or case-mix substantially decreases the magnitude of the cost differential.[3–5]

The present study re-examines the issue of indirect costs of graduate medical education and focuses specifically on whether a graduate medical education program fosters greater use of medical services and longer lengths of stay by comparing the teaching and nonteaching services of a single institution.

Methods

We compared lengths of stay, total hospital charges, and the use of cardiovascular procedures for patients treated for acute myocardial infarction in 1985 on the teaching and nonteaching services of a single hospital. We chose myocardial infarction as the "tracer" because it is a common disease, clinical indicators of disease severity are easily identifiable through chart review, and there are costly, disease-specific procedures for the diagnosis and treatment of coronary artery disease.

Setting

Our data derive from Abbott Northwestern Hospital, a private, secondary and tertiary care hospital with 780 beds staffed for adult patients. The hospital is affiliated with the University of Minnesota Medical School but has its own accredited internal medicine residency training program with 12 interns or residents in each year of a three-year program. Abbott Northwestern is not a member of the Council of Teaching Hospitals, and is considered a minor teaching hospital.

Description of the Training Program

The medical service was organized with a teaching and a nonteaching service, although there was no physical separation of the two services and all patients used the same nursing stations, ancillary services, etc. Attending physicians

This paper, submitted to the Journal August 31, 1989, was revised and accepted for publication February 12, 1990.

© 1990 American Journal of Public Health 0090-0036/90$1.50

admitted their patients to either the teaching or the nonteaching service, based on their own discretion, although beds on the teaching service were occasionally not available since the teaching service had a limited capacity. The attending physicians received the same reimbursement regardless of whether a patient was on the teaching or nonteaching service, so that there was no financial incentive involved in choice of service. Patients admitted to the nonteaching service were cared for solely by the private attending physicians, except in the rare case of medical emergencies, such as cardiac arrests, when residents were the only available physicians. Patients admitted to the teaching service were still the responsibility of the private attending physicians, although much of the decision-making was delegated to the teaching service ward teams. These teams were each comprised of an intern, a second- or third-year resident, a third-year medical student, and one of four internists who comprised the full-time teaching faculty. In their supervisory roles, the private attending physicians maintained routine contact with the teaching service ward teams through progress notes and informal meetings. The full-time teaching faculty conducted formal, bedside rounds after each admitting day (three hours per week per ward team), and each ward team had an additional two hours of teaching rounds per week with a separate "teaching-only" attending. These "teaching-only" faculty included internists and medical subspecialists who were not part of the full-time teaching faculty but who were part of the clinical teaching faculty of the University of Minnesota Medical School. Patient care on the teaching service was also supervised on a daily basis by three chief residents (in their 4th postgraduate year) assigned to the eight ward teams.

Facilities for Cardiac Care

Abbott Northwestern hospital had 73 critical care beds, 95 telemetry beds, a cardiac catheterization suite, and operating rooms for open heart surgery. Approximately 1,300 open heart surgeries and 900 percutaneous coronary angioplasties were performed each year at this hospital. The medical director of the critical care units was an internist who was not a cardiologist, and there were no standard orders or operating procedures that confined or limited the type of care that cardiac patients received. Patients could be cared for in the critical care units without a cardiologist attending and without a consultation from a cardiologist. Likewise, cardiac catheterization was performed under the direction of each individual cardiologist and not a catheterization laboratory director.

Patient Selection

We identified all patients discharged with a diagnosis of acute myocardial infarction (AMI) in 1985 from computerized discharge abstracts and reviewed the charts of these individuals. Of 325 patients with a discharge diagnosis of AMI we excluded 99 patients who had been transferred from another acute care facility because information concerning severity of illness could not be obtained consistently. We excluded 41 of the remaining 226 patients because chart review did not confirm a diagnosis of AMI (an elevated serum creatine kinase with a positive MB fraction, or sudden death within 24 hours of admission). Five patients with confirmed AMIs were excluded because complete information was not available for determining severity of illness. The final study cohort of 180 patients therefore included all patients directly admitted to the hospital in 1985 with a confirmed diagnosis of AMI for whom accurate severity of illness information was available. In analyses of hospital charges we included only 177 patients because charge data were not available for three patients.

Data Collection

Data were collected from chart review, computerized discharge abstracts, and the accounting office. All charts were reviewed by one of us (ISU) to collect information on age, race, sex, whether the attending physician was a cardiologist, and, if the attending was not a cardiologist, whether the patient was seen by a cardiologist in consultation. To assess the general severity of acute medical illnesses, each patient was classified by a modified APACHE II score.[16] Because age was a separate variable in our analyses we excluded points for age from the APACHE II score. We recorded the number of diagnoses listed on the discharge summary as an approximation of comorbid disease. To assess the severity of cardiac illness we noted whether each patient had a history of a previous AMI, whether there was evidence of congestive heart failure on admission, and whether during the hospitalization there was recurrent chest pain, shock, cardiac arrest, sustained ventricular dysrhythmia, or severe conduction system disturbance (2nd or 3rd degree atrioventricular block or severe bradycardia).

From the discharge abstracts and the accounting office, we obtained data on primary and secondary payor, mortality, length of stay, total hospital charges, and the use of the following cardiovascular procedures: percutaneous coronary angioplasty, coronary artery bypass surgery, cardiac catheterization, Swan-Ganz catheterization, temporary pacemaker placement, and echocardiograms. We used hospital charges as an estimate of costs. Unit charges were identical on the teaching and nonteaching services and therefore total hospital charges should be a good proxy for relative costs even if they are not equivalent to absolute costs. Because angioplasty and bypass surgery may be viewed as different methods of myocardial revascularization these two outcomes were also combined to form a composite variable. Three patients had coronary angioplasty fail and therefore had bypass surgery as well. These patients were counted as having only one episode of myocardial revascularization.

Data Analysis

Our primary goal was to compare procedure use, length of stay, and total charges between the teaching and nonteaching services. To adjust for potential confounding due to differences in severity of illness and demographic characteristics, we performed a two-stage analysis using propensity scores as described by Rosenbaum and Rubin.[17,18]

A "propensity score," defined as the probability of being on the teaching service as a function of the confounding variables, was calculated for each patient. Patients were then stratified by propensity score and outcomes were compared using the techniques for stratified data described below.

We used a logistic regression model to calculate the propensity scores as a function of 11 potential confounders: age, sex, type of insurance (health maintenance organization or other), history of previous myocardial infarction, APACHE II score, recurrent chest pain, congestive heart failure, atrioventricular block or bradycardia, shock, cardiac arrest or sustained ventricular dysrhythmia, and the number of comorbid diagnoses. There was a linear relationship between age and the probability of being on the teaching service, so age was used as a continuous variable in the model. Interaction terms added little to the predictive ability of the model and were excluded. The patients were then grouped into five strata on the basis of the probabilities

derived from the logistic model. For example, as a function of their severity of illness and other characteristics, patients in the lowest stratum had on average a 23 percent chance of being on the teaching service while patients in the highest stratum had a 78 percent chance of being on the teaching service.

Summary estimates of differences in hospital charges, lengths of stay, and procedure use between the teaching and nonteaching service were calculated using weighted averages across the five strata based on propensity scores. These summary estimates are therefore average differences that are adjusted for differences in patients' severity of illness and demographic characteristics.

Average differences in mean length of stay and charges were estimated by weighting each stratum specific difference by the inverse of the variance of the difference.[19] Average differences in median length of stay and charges were estimated by weighting each stratum specific difference in median length of stay or charges by the number of observations in that stratum, thereby producing a standardized median difference.[19] A stratified Wilcoxon rank sum test was used to test significance since length of stay and charges did not have normal distributions.[20]

Adjusted differences in procedure and mortality rates were calculated as standardized rate differences, again using the number of observations in each stratum as the weight, because several strata had marginal totals of zero.[19] Ninety-five percent confidence intervals (CI) for these standardized rate differences were based on the chi-square test statistic.[19]

To determine whether differences in resource use between the teaching and nonteaching service could be due to differences in the number of patients on each service who had a cardiologist as their attending physician, or to differences in the frequency of consultation by a cardiologist on each service, we controlled for these factors in a separate analysis. In this analysis we added dichotomous variables representing the specialty of the attending physician (cardiologist or not) and whether a patient had a cardiology consultation (yes or no) to the logistic regression model defined above, producing a second propensity score model based on 13 potential confounders. Patients were again divided into five strata on the basis of propensity scores and the above noted techniques for stratified analysis were employed to calculate weighted averages for procedure rates, length of stay and charges.

To assess the importance of outliers, we repeated our analyses excluding four patients (all on the teaching service) who had a length of stay greater than the 1985 Medicare outlier limit, which was 35 days.

The 95 percent CI for all univariate comparisons were based on the chi-square statistic[21] for categorical variables and Student's t-distribution[21] for continuous variables.

Results

Patient Characteristics

The number of patients admitted to the teaching and nonteaching services, their clinical characteristics, and the percentages enrolled in health maintenance organizations, cared for by a specialist in cardiology or seen by a cardiologist in consultation, are indicated in Table 1.

Although age and sex distributions were similar for the two groups, patients on the teaching service were generally more ill. Specifically, they had more comorbid diagnoses and more frequently had congestive heart failure on admission, recurrent chest pain, and cardiac arrest or sustained ventricular dysrhythmia.

Severity of Illness and Resource Use

The univariate associations of severity of illness with procedure use, length of stay, total charges, and mortality are presented in Table 2. Generally, the severity of illness indicators were well correlated with resource use and therefore seem to be reasonable covariates to use when controlling for severity of illness in our analyses. The patterns of procedure use, length of stay, charges and mortality conform to conventional clinical wisdom.

Resource Use and Teaching Status

Procedure rates, length of stay, hospital charges, and mortality on the teaching and nonteaching services are presented in Table 3. Patients on the teaching service had significantly fewer cardiac catheterizations and underwent myocardial revascularization less frequently. However, they had more frequent use of echocardiography. These differences persisted after adjustment for severity of illness and demographic characteristics. There was no difference in the

use of Swan-Ganz catheterization or temporary pacemakers between the two services.

Before adjusting for severity of illness and demographic characteristics there were equivocal differences in length of stay between the two services; the teaching service had a higher mean length of stay but a lower median length of stay. After adjustment, the teaching service clearly had shorter lengths of stay. For hospital charges, patients on the teaching service tended to have higher charges before adjusting for severity and demographic characteristics, but this pattern reversed after adjustment for these factors.

The differences in length of stay and hospital charges persisted when outliers were excluded from the analysis. The adjusted mean length of stay for patients on the teaching service was 1.1 days shorter and the adjusted median length of stay was 0.5 days shorter ($p = 0.009$). Adjusted mean charges were $2,257 less and adjusted median charges were $1,653 less ($p = 0.07$).

The differences in resource use between the teaching and nonteaching services also persisted when we controlled for the specialty of the attending physician (cardiology or other) and whether a patient was seen in consultation by a cardiologist. The teaching service still had a lower use of cardiac catheterization, i.e., −11 percent (95% CI: −22, 0), and tended to have less myocardial revascularization, i.e., angioplasty −3 percent (95% CI: −8, 2); coronary bypass surgery −3 percent (95% CI: −11, 5); either −5 percent (95% CI: −13, 3). Controlling for these same variables minimized differences in lengths of stay and hospital charges. The teaching service had an adjusted mean length of stay that was 0.1 days shorter and an adjusted median length of stay that was 0.5 days shorter ($p = 0.09$). Adjusted mean charges were $16 higher on the teaching service, while adjusted median charges were $508 lower on the teaching service ($p = 0.46$).

Despite differences in resource use, in-hospital mortality on the two services was comparable. After adjusting for demographic characteristics and severity of illness, patients on the teaching services had a mortality rate that was 4 percent (95% CI: −10, 18) higher than for patients on the nonteaching service.

Discussion

Our data do not support the view that care on teaching services necessarily entails greater use of resources than care on nonteaching services, when adjusted for severity of illness. On the contrary, these data show that once adjustments were made for differences in severity of illness, patients on a teaching service had shorter lengths of stay and received a conservative type of care that used less cardiac catheterization and myocardial revascularization.

There may be several reasons why our results differ from those of previous investigators. First, our data were collected in 1985 and almost all previous studies have analyzed data collected prior to 1981.[2-10] We believe that emphasis on efficiency and "cost effectiveness" in academic medical centers is more common now than it was during the late 1970s and early 1980s. This may be especially true for the hospital we studied, since the Twin Cities has a very competitive health care market.

A second explanation may be that patients in teaching hospitals are more severely ill and much of this difference in severity may not have been controlled for by previous investigators using methods of DRG (diagnosis related group) case-mix adjustment. We used clinically relevant indicators of severity that were specific to one illness—acute myocardial infarction. The changes in patterns for length of stay and charges that we found before and after adjustment for severity of illness support the conclusion that there is significant variation in disease severity between teaching and nonteaching patients that may not be adequately controlled for by simple case mix adjustment.

A third explanation may be that the setting of our study allowed us to better isolate the effect of a teaching program on resource use. In our single hospital setting the primary difference between the teaching and nonteaching services was the presence of the teaching program and not other institutional or organizational characteristics. Results from previous studies which compared separate teaching and nonteaching hospitals may have been confounded by systematic differences between the two types of hospitals in terms of organization and other characteristics not directly related to teaching.[3,5,8,10] Even those previous studies which compared teaching and nonteaching services within a single institution may have been confounded by organizational differences since most studies evaluated physically separate patient care units.[2,4,6,7,9]

Certain characteristics of the decision-making process on the teaching services may also have influenced the pattern of procedure use we found. Before a patient on the teaching service underwent a procedure, the housestaff, teaching attending, private attending, and the cardiologist came to a working agreement on a treatment plan. It is possible that this interaction decreased utilization in a way analogous to mandatory second opinion programs.[23,24]

Nevertheless, there are several limitations to this study. First, patients were not randomly assigned to the teaching and nonteaching services and therefore differed in a variety of characteristics. It is possible that patients admitted to the teaching service were in other ways less "appropriate" candidates for procedures than patients on the nonteaching services. We did not have sufficient data to ascertain the appropriateness of, or indications for, individual procedures, but we did attempt to collect data on and control for those patient characteristics that correlated with and likely influenced patient management. Therefore, we feel that differences in procedure use between the two services are unlikely to be related to the severity of acute cardiac disease, and are more likely to be due to differences in practice style on the teaching and nonteaching services that are independent of disease severity. However, we cannot exclude the possibility that differences in unmeasured, clinically relevant characteristics between patients on the teaching and nonteaching services accounted for our results.

Second, it is possible that variations in the practice style of a few attending physicians accounted for our results. However, 71 attending physicians had patients in our study and the mean number of patients per attending physician was 2.5 (range 1–11).

A third potential problem with our findings is that the records on the teaching and nonteaching services may have contained systematically different amounts and detail of information regarding severity of illness. The physician-reviewer who abstracted all the charts did not note such a discrepancy, especially for the parameters of severity and utilization that we collected. Therefore we do not feel that our findings are an artifact of chart completeness.

Finally, we decided to study only one hospital and one disease in an effort to control for as many confounders as possible. This limits our ability to generalize our results to other settings and other diseases. An analysis of the management of other illness which have less stereotyped patterns of care or which have fewer options for very specialized procedures may show different results. While it is also possible that the teaching service we studied may be atypical and not representative of teaching services at other types of institutions, we feel that the nature of the internal medicine training program we studied was very similar to that of most university-based programs. It is also likely to be representative of those found in other nonCOTH (Council of Teaching Hospitals) minor teaching hospitals which in total comprise approximately 72 percent of all teaching hospitals in the country and have 19 percent of all residents.[25] These nonCOTH minor teaching hospitals would therefore receive approximately 20 percent of Medicare's payments for indirect medical education.[26]

Overall, this study suggests that graduate medical education does not universally lead to longer lengths of stay and greater use of medical resources. It may therefore be unwarranted to equate the cost differences between teaching and nonteaching hospitals with nonessential clinical expenditures generated by graduate medical education. This does not imply that teaching hospitals have the same costs as nonteaching hospitals. Graduate medical education may lead to "indirect" costs that are associated with teaching such as floor space devoted to conference rooms, larger medical libraries, and support for teaching faculty. The presence of graduate medical education may encourage teaching hospitals to have more active programs for nursing education and continuing education for staff physicians. Teaching hospitals may also require a more sophisticated organizational structure and higher level of technical support because of the academic mission which leads to caring for patients who require extraordinarily specialized and highly technical care. Previous studies have shown that hospitals which accept a large number of transfer patients have higher average costs per case than hospitals receiving few transfer patients.[27] Teaching hospitals may constitute a large percentage of such hospitals because of specialized services that attract referrals. Other reasons for higher costs in teaching hospitals may not be directly related to graduate medical education at all.

For example, there may be important differences in the socioeconomic characteristics of patients in teaching hospitals that increase resource use and bad debt.[28]

Medicare's supplementary payment to teaching hospitals to cover the indirect costs of graduate medical education is already controversial and has been reduced by 30 percent since 1983. Further reduction is now under serious consideration. Other payers are also questioning the high costs of care in teaching hospitals. The results of this study suggest that these costs may not be a function of unnecessarily longer lengths of stay and greater use of health care resources. We postulate that much of the higher costs noted in teaching hospitals may now come from the overhead expense of providing and developing specialized services or from differences in the patient populations of teaching and nonteaching hospitals that are not accounted for in DRG case-mix adjustments. In order to institute proper reform of reimbursement for graduate medical education, further work is needed to define more accurately the components of graduate medical education that currently influence health care costs.

ACKNOWLEDGMENTS

Call for Presentations at 1991 Annual Conference of AHA Section for Psychiatric and Substance Abuse Services

The American Hospital Association Section for Psychiatric and Substance Abuse Services invites proposals for presentations at their annual conference, "Changes and Challenges, Management of Psychiatric and Substance Abuse Services." The conference, which will be held Jun 5–7, 1991 in Boston, attracts hundreds of multidisciplinary mental health professionals from hospital-based psychiatric and substance abuse programs.

Proposals for presentations are requested which address such topics as: cost-effective service delivery methods, state-of-the-art technology, quality assurance issues, treatment of special populations, and strategic planning, as well as others. The deadline for submitting proposals is October 1, 1990. For further information and a presentation application form, please call Rebecca Chickey, 312/280-6650.

The Effects of Workplace Health Promotion on Absenteeism and Employment Costs in a Large Industrial Population

ROBERT L. BERTERA, DRPH

Abstract: We evaluated the impact of a comprehensive workplace health promotion program on absences among full-time employees in a large, multi-location, diversified industrial company. A pretest-posttest control group design was used to study 41 intervention sites and 19 control sites with 29,315 and 14,573 hourly employees, respectively. Blue-collar employees at intervention sites experienced an 14.0 percent decline in disability days over two years versus a 5.8 percent decline at control sites. This resulted in a net difference of 11,726 fewer disability days over two years at program sites compared with non-program sites. Savings due to lower disability costs at intervention sites offset program costs in the first year, and provided a return of $2.05 for every dollar invested in the program by the end of the second year. These results suggest that comprehensive workplace health promotion programs can reduce disability days among blue collar employees and provide a good return on investment. (*Am J Public Health* 1990; 80:1101–1105.)

Introduction

Health education has significant potential for reducing risk factors.[1–13] The effectiveness of workplace health promotion programs in reducing health risks has been demonstrated in the areas of high blood pressure control[14–16] and smoking cessation.[17–19] The evidence is more tentative in other areas of lifestyle change.[20–35]

Health education in the workplace is growing rapidly, driven by the promise of providing several non-economic,[33,36–38] as well as economic benefits.[18,38–44] Some authors emphasize the need for cost benefit and cost effectiveness analyses in order to examine the cost-effectiveness of workplace health promotion.[18,37,40,41,45] Others point out the limitations to the existing literature.[38,39,41]

The purpose of this study was to evaluate the impact of a comprehensive workplace health promotion program on illness absences not related to occupational causes.

Methods

Program Description

The program includes five core elements: training for site coordinators; a Health Promotion Activity Committee (HealthPAC); Orientation and Publicity; Health Risk Appraisal; and a variety of self-directed and group health education opportunities. These were first pilot tested in 1981 and 1982 at two manufacturing locations, refined, and then offered at the 41 intervention sites beginning in late 1983 and early 1984.

The program is introduced and administered by a network of site and departmental coordinators. Approximately 60 percent of these individuals are non-medical personnel selected for their communication skills, interest in health enhancement, and organizational abilities; in most cases, they serve part time in conjunction with their regular jobs. The remaining 40 percent are site medical personnel including nurses, physicians, and physician assistants.

At each location, a Health Promotion Activity Committee (HealthPAC) consisting of five to 15 employees from all levels of the organization assists in planning, publicity, and implementation.

The corporate health promotion staff offers a variety of three-day workshops designed to provide program guidelines, materials, and support for coordinators and HealthPACs. A quarterly newsletter keeps coordinators, committee members and management informed about site activities, new programs, and progress toward program objectives.

All program participants complete a voluntary, computer-scored health risk survey (available on request to author) containing 36 items on health status, personal habits, and lifestyle. Assistance is provided for interpreting appraisal results in groups using a videotape explanation, and individually through consultation with site medical personnel for all employees who request it. A copy of the appraisal is filed with the medical record for review during periodic medical evaluations which are offered to all employees at one, two, or three year intervals, based on age.

Health promotion activities include a variety of group and self-directed opportunities. Four- to 10-week class cycles provide opportunities at lunchtime or after shift to raise awareness or learn new skills. Topics for group and self-directed programs include smoking cessation, fitness, weight control, lipid control, stress management, and healthy back.

All employees receive a bi-monthly health and fitness magazine that helps keep employees and family members informed about current health and wellness developments. Challenges and incentive programs attempt to involve large numbers of employees in fitness, weight control, and smoking cessation activities. Cafeterias and vending machines offer heart healthy foods. Employees can check and record their own blood pressure and weight at machines and scales located in high traffic locations.

Certain program components were offered on company time including: program orientation activities, Health Risk Appraisal meetings, individual counseling, and health promotion activities presented to employees during safety meetings. The time allowed for these activities varied from 30 minutes to three hours, depending on employee interest and site commitment to employee health improvement. All employees must attend regular safety meetings on company time. Some of these meetings introduce and reinforce topics important to employee wellness such as: stress management, dental health, weight control, fitness, healthy back, high blood pressure control, nutrition guidelines, and smoking cessation. Safety meetings usually occur at least monthly and last from 15 to 60 minutes.

Program Costs and Benefits

Actual program costs, disability wage costs, and disability wage savings were analyzed for the baseline year and two program years. Health promotion program costs include all expenses in 1986 dollars for: staff and committee time; instructors and group leaders; educational materials; publicity and promotion; health risk appraisals; and recognition awards and incentives. Program costs did not include: office space and utilities; fitness equipment (only a few sites had any at the time of the study); and the value of employee time when attending activities during working hours.

Disability wage costs included actual wages and benefits paid to hourly employees in 1986 dollars for days of absence due to illness. Savings were calculated as the difference between disability wages paid at the end of the first and second program years subtracted from disability wages paid in the baseline year, prior to the program's introduction. Disability wage costs and savings exclude other costs that may be related to absenteeism such as health care claims and replacement worker expenses.

Study Population and Design

The study population consisted of hourly employees who were part of the US workforce in a large, diversified manufacturing company. White collar employees were excluded from the study because the major outcome measure—disability days due to non-occupational illness—was recorded only for hourly employees. The hourly workforce had the following characteristics: more than three-fourths (82.7 percent) male; 16.1 percent Black; and more than one-third (41.0 percent) were 40 or more years of age.

We used a pretest-posttest equivalent control group design.[46] Out of 100 locations that were providing comprehensive health promotion services, 60 were included in this study because they had at least 100 hourly employees on site. This excluded smaller sites from the study such as unit plants, warehouses, and transfer depots, as well as predominantly white collar locations such as sales offices, service units, and research centers. All study sites followed consistent policies on disability leave and reporting throughout the study. Although site-specific data on turnover rates were not available, the company has a long tradition of very low employee turnover.

The intervention sites consisted of 41 locations which elected to initiate the health promotion program by June 1985 and met the above inclusion criteria. All sites had to obtain prior approval to initiate the health promotion program by submitting a written implementation plan to the corporate health promotion manager. This review process made it possible to identify the study's control sites. The control sites consisted of 19 locations that had not adopted the program by June of 1985.

The two study groups were compared for equivalence on a number of demographic and social characteristics at baseline. The 41 program sites did not differ significantly from the 19 non-program sites in terms of the average number per site of: employees; males; employees 40 years of age or older; or the total number of hourly or salaried employees (Table 1).

The analysis is based on absenteeism data from 43,888 hourly employees from January 1984 through December 1986. The 41 program sites employed 29,315 hourly employees while the 19 non-program sites employed 14, 573 hourly employees.

TABLE 1—Demographic Profile Of Hourly Employees at Health Promotion Program Sites vs Non-program Sites

Mean Number per Site[a]	Study Groups[b] Program Sites (N = 41)	Non-Program Sites (N = 19)
Total Hourly Employees	715	767
Males	582	625
Age 40 or Older	325	324
Total Number of Hourly Employees	29,315	14,573
Total Number of Employees (Hourly and Salary)	42,435	22,116

[a]Based on 1984 averages per site for hourly employees except where noted as totals for the study group.
[b]No significant differences by t tests, 2 tail, separate variance estimate.

Unit of Analysis and Measurement of Outcomes

The primary outcome variable, using the sites as units of analysis, was the annual mean number of disability days per hourly employee. Days lost due to disability is defined as a measure of absenteeism that includes all illnesses not related to occupational causes. Disability days are recorded on time cards signed by supervisors and submitted to site time keepers for payroll purposes. Site disability days are reported quarterly to the corporate Compensation and Benefits Division which aggregates site data into annual reports.

Another outcome variable was the cost of wages, compensation, and benefits paid in 1986 dollars for days absent due to illness. For several years before this study began, all 60 study locations reported actual annual costs of wages, compensation, and benefits per hourly employee as part of an ongoing corporate accounting system separate from the health promotion program.

The health promotion program costs were obtained from two sources: 1) many items such as educational materials, supplies, health risk appraisals, and incentive awards were obtained from the corporate program, which provided expense records when sites were charged back for these goods and services; 2) sites were asked to submit annual budgets including information on staff and committee time. These sources were used to calculate the average annual program expenditures per hourly employee at each of the 41 intervention sites. The urban Consumer Price Index was used to convert health promotion program costs and disability wage costs into 1986 dollars and thus control for the effects of inflation from 1984 through 1986.

Results

The health promotion program began at the 41 intervention sites between November 1983 and June 1985. Most sites began the program in the first quarter of 1984; however, due to start-up delays, the program was actually available to employees an average of 20 months per site during the two-year study period.

Disability Days

As shown in Table 2, employees at program sites experienced a somewhat higher average number of days lost due to disability in the baseline year (1984). In the first year after the program was introduced (1985), the average number of disability days dropped 10.5 percent at program sites while it increased 1.9 percent at non-program sites.

TABLE 2—Mean Disability Days Lost by Hourly Employees by Program Year for Program and Non-program Sites

Year	Disability Days Lost by Study Group	
	Program Sites (N = 41)	Non-Program Sites (N = 19)
1984 (Baseline Pre-Program)	5.7	5.2
1985 (Year 1)	5.1	5.3
1986 (Year 2)	4.9	4.9
1984–1986 (decline)*	0.7	0.3

*Differences is 0.4 disability days (95 percent confidence interval 0.3, 0.5).

TABLE 3—Mean Disability Days by Hourly Employees Baseline Year (1984) vs Program Years One and Two for Sites with High vs Low Participation

Year	Disability Days Lost by Site Participation Level	
	High (N = 20)	Low (N = 21)
1984 (Baseline Pre-Program)	5.7	5.5
1985 (Year 1)	4.9	5.2
1986 (Year 2)	5.0	4.9
1984–1986 (decline)*	0.7	0.6

*Difference is 0.1 disability days (95 percent confidence interval 0.03, 0.23).

By the end of the second year, disability days dropped 14.0 percent at program sites and 5.8 percent at non-program sites. This represents 0.7 fewer disability days at program sites and 0.3 fewer days at non-program sites. The difference is 0.4 disability days per hourly employee (95 percent confidence interval 0.3, 0.5 days), which resulted in a savings of 11,726 fewer disability days at program sites compared with non-program sites over two years. This savings is the equivalent of 49 person years of effort that can be spent to produce goods and services.

The data suggest that the health promotion program had some influence on lowering disability days among hourly employees. It should be noted that other potential influences on disability statistics, such as early retirement programs and changes in medical insurance plans, were implemented simultaneously at both program and non-program locations during this period, thus providing some control for these external influences.

Disability Days by Participation Level

Although all 41 program sites met company health promotion guidelines (see Program Description, above), sites probably varied in the resources that they allocated to the program. Due to the number of sites, only limited anecdotal information was obtained in the course of the study to suggest resource variation as a confounding factor; one indirect indicator of how employees perceived the program was participation rates. Participation was measured by the number of employees who completed the Health Risk Survey form. Employees who completed the 36-item risk survey received a computer-scored Health Risk Appraisal within about 30 days.

Program sites where 50 percent or more of employees completed the Health Risk Survey had an average survey completion rate of 70.6 percent (CI = 69, 72), and are referred to as "High Participation" sites (N = 20). Program sites where less than 50 percent of employees completed the Health Risk Survey averaged only a 30 percent completion rate (CI = 26, 34), and are classified as "Low Participation" sites (N = 21).

One indicator that demonstrates differences in the intensity of program activity at high versus low participation sites was the variety of on-site classes offered. Sites that obtained a "high" response to the Health Risk Appraisal offered 6.2 topics, compared with 4.2 topics at low participation sites (difference 2.0, 95 percent CI = 1.56, 2.44).

As shown in Table 3, mean disability days declined in the first year by 14.0 percent at high participation sites and by 5.4 percent at low participation sites. By the end of the second year, disability days had declined 12.3 percent at program sites and 10.9 percent at non-program sites. This reflects a mean difference of 0.1 disability days (95 percent CI = 0.03, 0.23 days) between the two participation levels.

These data suggest that while higher participation was associated with greater declines in disability days in the first year, the association was not maintained in the second year. Table 4 indicates that there were about 50 percent more hourly employees at low participation than at high participation sites. It is possible that participation level was influenced by site size in a way that enabled smaller sites to gain higher participation and lower disability in the first year due to simplified start up logistics. By the second year, however, larger sites could have offered the program to more of their employees, thus reducing the first year differences that appeared to favor high participation sites. Another fact that supports this view is that indicators of participation were heavily dependent on first program year activity, again making it more likely that smaller sites would be classified as high participation sites.

Health promotion program costs were higher than in the first program year ($1.4 million) than the second year ($.7 million). This reflects higher initial investments of staff time, coordinator and committee time, training, publicity, and educational materials and incentives, some of which were not repeated in the second year. Savings due to lower disability costs were enough to offset program costs in the first year, where every dollar invested in health promotion yielded $1.11 in lower disability costs; in the second program year, every $1.00 spent on health promotion yielded disability savings of $2.05 (Table 5). Total return on investment over two years averaged $1.42 in lower disability wage costs for every $1.00 invested in health promotion.

TABLE 4—Demographic Indicators for Hourly Employees at Program Sites with Low vs High Participation

Mean Number per Site[a]	Site Participation Level[b]	
	High (N = 20)	Low (N = 19)
Total Hourly Employees	568	905
Males	446	759
Age 40 or Older	242	439
Total Number of Hourly Employees	11,927	18,110
Total Number of Employees (Hourly and Salary)	19,257	25,252

[a]Based on 1984 averages per site for hourly employees except where noted as totals for the study group.
[b]No significant differences by t tests, 2 tail, separate variance estimate.

TABLE 5—Program Costs and Disability Savings[a] by Program Participation Level and Year

Program Analysis	All Program Sites (N = 41 Sites)	Site Participation Level: Low (N = 21 Sites)	Site Participation Level: High (N = 20 Sites)
Year 1 (1985)			
Costs	$1,436,965	$ 736,031	$ 700,933
Savings	1,596,877	708,069	888,808
Return on Investment[b]	$1.11	$ .96	$1.27
Year 2 (1986)			
Costs	$ 714,312	$ 366,075	$ 348,237
Savings	1,463,524	641,632	821,891
Return on Investment[b]	$2.05	$1.75	$2.36
Combined (1985 & 1986)			
Costs	$2,151,277	$1,102,107	$1,049,170
Savings	3,060,401	1,349,701	1,710,699
Return on Investment[b]	$1.42	$1.22	$1.63

[a]All Costs and Savings figures are in 1986 dollars.
[b]Based on disability savings divided by program costs.

Total return on investment over two years varied by program participation level, with high participation sites saving $1.63 in lower disability costs for every dollar invested over two years, versus $1.22 for low participation sites (Table 5).

These return-on-investment data are conservative estimates because they exclude other potential savings that may be associated with lower absenteeism including lower costs for: company health care claims; replacement workers; and employee out-of-pocket health care expenses.

Discussion

Intervention sites self-selected themselves by initiating comprehensive employee health promotion activities prior to June 1985. This decision may have been linked to factors that could have predisposed self-selected sites to reduce disability days through means other than health promotion.

If present, this bias could lead to over-estimating the potential impact of the program. Future studies could control this potential bias by randomly assigning sites to intervention and control conditions.

The control sites consisted of 19 locations that had not adopted the comprehensive program by June 1985. However, a few of the 19 control locations may have initiated portions of the program after June 1985 and thus received partial interventions from July 1985 through December 1986. This potentially dilutes the intervention effect which may have been reflected in the second-year absenteeism declines for control sites, and probably produces an underestimate of the program's potential impact. No systematic information was collected on the nature or extent of potential control site contamination. The extensive communication networks and decentralized decision-making in a large, diversified company makes it difficult to measure and control such effects.

Disability days were tracked for three years including the baseline year. Longer follow-up periods would be desirable to measure maintenance effects. Unfortunately, the tracking system for disability days was discarded in 1987 as part of a restructuring of human services resources within the company.

Site employee participation levels were estimated by the number who completed the health risk appraisal. This is an indirect but convenient measure of perceived interest and quality. While some evidence exists that the number of activities offered on the site is related to the risk appraisal completion, future studies should seek additional information on program participation, activities, and expenditures. The measurement and attribution of potential program impacts could also be improved by obtaining information on geographic or intergroup variations of employee turnover, job satisfaction, and other measures of attitudes or beliefs that could affect absenteeism patterns.

Recent published reports, while not using absenteeism as an outcome, have reported savings associated with comprehensive health promotion programs in the workplace. In a study of Johnson & Johnson's comprehensive approach, inpatient hospital insurance costs compared to controls[47] were nearly $1 million lower over five years. These savings were attributed to lower rates of increase in the number of hospital days and in the number of admissions among employees at program sites.

In a study of a comprehensive health promotion and wellness education at Blue Cross-Blue Shield subscriber companies, employees with the program claimed 24 percent fewer health insurance dollars over five years compared to similar employees who were not receiving the program.[48] The savings in lower health care insurance costs produced a return on investments of $1.45 for each dollar spent on the program.

These studies and our results suggest that comprehensive workplace health promotion programs can return $1.45 in lower hospital insurance costs and another $1.42 in lower disability wage costs for every dollar invested in health promotion. If these findings can be confirmed in other studies, it appears that health promotion programs are good business because they provide a favorable return on investment while helping to improve indicators of health among blue collar employees.

USEPA to Sponsor International Symposium on Radon

The United States Environmental Protection Agency has announced the dates for the International Symposium on Radon and Radon Reduction Technology will be April 2–5, 1991, in Philadelphia, Pennsylvania, and has issued a call for papers with the theme being 'A New Decade of Progress.'

The symposium will provide a forum for the exchange of technical information on radon and radon reduction technology in the indoor environment. The major topics considered for the symposium will be: experience in the development and application of radon reduction and radon-resistant construction techniques, the measurement of radon and radon progeny, and the assessment of radon-derived health impacts.

Topics of greatest interest are: Radon Control, Measurement Methods (air and soil), Health Issues, Foreign and Domestic Radon Programs and Policy Issues, Radon Surveys, Public Information and Education, Radon in the Natural Environment.

Abstracts of 150 words or less should be submitted by September 30 to: Timothy M. Dyess, US-EPA, AEERL/Radon Mitigation Branch, MD-54, Research Triangle Park, NC 27711. Papers should provide study results; however, theoretical discussions of concepts and mechanisms will also be considered. Abstracts will be screened by the sponsors and papers will be solicited to cover areas of special concern. Notification of acceptance of papers will be done by November 15, 1990, after which the author will be required to submit an original and five copies of the paper by January 31, 1991.

Caffeine-Containing Beverages, Total Fluid Consumption, and Premenstrual Syndrome

ANNETTE MACKAY ROSSIGNOL, ScD, AND HEINKE BONNLANDER, RN, MSN

Abstract: The main objective of this study was to evaluate whether daily consumption of caffeine-containing beverages is related to the prevalence and severity of premenstrual syndrome apart from any effects of daily total fluid consumption. A secondary objective was to determine whether daily total fluid consumption itself is related to premenstrual syndrome. The study is based on 841 responses to a questionnaire probing menstrual and premenstrual health, and daily fluid consumption, which was mailed to female university students in Oregon. Analysis of the data revealed that consumption of caffeine-containing beverages was strongly related to the prevalence of premenstrual syndrome. Among women with more severe symptoms, the relation between consumption of caffeine-containing beverages and premenstrual syndrome was dose-dependent, with prevalence odds ratios equal to 1.3 for consumers of one cup of a caffeine-containing beverage per day and increasing steadily to 7.0 for consumers of eight to 10 cups per day. The effects were apparent among both caffeine-containing tea/coffee consumers and caffeine-containing soda consumers. The observed effects were only slightly reduced when daily total fluid consumption was controlled. Daily total fluid consumption also was related to the prevalence of premenstrual symptoms although the effects were large only for consumers of 13–19 cups of fluid per day (the largest amount studied). (*Am J Public Health* 1990; 80:1106–1110.)

Introduction

Previous investigations have indicated that the consumption of caffeine-containing beverages is strongly related to the prevalence and severity of premenstrual syndrome (PMS), and that such effects exist for a wide variety of premenstrual symptoms.[1–4] Further work demonstrated that the association between premenstrual symptoms and consumption of caffeine-containing beverages occurs even among women who lack other putative causes of the syndrome.[5] Such putative causes included alcohol use, cigarette use, lack of exercise, oral contraceptive use, and a diet high in beef and refined sugar products.[6–18]

One possible explanation for the observed association between consumption of caffeine-containing beverages and premenstrual symptoms is that consumption of these beverages is related to daily total fluid consumption, and that it is daily total fluid consumption which is causally related to premenstrual symptoms. Such an explanation might be consistent with the retention of fluid experienced by many women who report premenstrual symptoms.

This study was undertaken to assess the relation between premenstrual syndrome and caffeine-containing beverage intake, and between premenstrual syndrome and total fluid intake, controlling for any confounding effects attributable to the other variable. In addition, we wanted to describe the dose-response relation between premenstrual syndrome and consumption of caffeine-containing beverages and of total fluid, and to discover which types of caffeine-containing beverages might exert an effect.

Methods

Study Population and Data Collection

The study was conducted at a public university in Oregon. Eligible subjects were the 1,419 currently enrolled, female students who resided in any of the university's residential dormitories.

In October 1988, each eligible student was sent a questionnaire, together with a cover letter explaining the general nature of the study (a study of women's health) and requesting her participation. The questionnaire solicited information about the presence and severity of premenstrual symptoms and of menstrual symptoms, demographic characteristics, use of over-the-counter drugs containing caffeine, and typical daily consumption of beverages including caffeine-containing beverages. The questions pertaining to premenstrual symptoms asked each respondent to indicate whether she experienced premenstrual symptoms and, if she did, to score the severity (mild, moderate, or severe) of each in a list of 10 premenstrual symptoms plus an "other symptom" category. To reduce the likelihood that the study participants would suspect the hypotheses under investigation, we included questions about menstrual health similar in number and detail to those probing premenstrual health. A definition of the syndrome, which emphasized the timing of symptoms with respect to the onset of menses, was included in the questionnaire.

The questions pertaining to daily beverage intake asked for the number of cups, defined on the questionnaire as "eight ounces, or one measuring cupful," of each in a list of 11 beverages plus an "other beverage" category the respondent consumed during a typical day. One of the 11 beverages was water.

Eight-hundred-and-sixty-nine women (61 percent) returned the questionnaire after two mailings. (The second mailing was conducted in January 1989.) The data for 28 women subsequently were excluded from the data analysis: two women reported having endometriosis, four women did not menstruate on a regular basis, and 10 women did not provide information on the presence of premenstrual symptoms or on the daily consumption of beverages. An additional 12 respondents were excluded because their daily consumption of caffeine-containing beverages was between 11 and 30 cups, making the cup-specific prevalence odds estimates unstable (as described in the section on data analysis). These exclusions left data on 841 women for analysis. Ninety-six per cent of these women were between the ages of 18 and 22 years.

Data Analysis

We estimated the premenstrual syndrome prevalence odds ratios, the odds of having premenstrual syndrome among "exposed" women divided by the odds among "unexposed" women, for five levels of daily consumption of caffeine-containing beverages (one cup, two to four cups, five cups, six or seven cups, and eight to 10 cups) and for four levels of daily total fluid intake (six or seven cups, eight to 10 cups, 11 to 12 cups, and 13 to 19 cups). These intervals were determined empirically on the basis of the uniformity of the premenstrual syndrome prevalence odds ratio point estimates for each level of consumption within an interval. For the three subjects who used caffeine-containing drugs on a daily basis, the estimates of the number of cups of a caffeine-containing beverage consumed each day were increased. The amount of increase equaled the equivalent number of cups of a caffeine-containing beverage for the caffeine content of the drug. The equivalency was determined by the information provided on each drug's packaging material. There were too few subjects who reported consuming more than 10 cups of a caffeine-containing beverage each day, or more than 19 cups of total fluid each day, to provide information for higher levels of consumption. Daily total fluid consumption was calculated by summing the numbers of cups of beverages consumed each day for each of the 11 listed beverages plus the "other" beverage category.

Confidence intervals for the prevalence odds ratios were based on Miettinen's test-based procedure, using the programs of Rothman and Boice.[19]

The overall trend in the data relating premenstrual symptoms and caffeine-containing beverages intake, and premenstrual symptoms and total fluid intake, was tested using the method described by Mantel.[20] The method of maximum likelihood was used to estimate the slope, and standard error for the slope, for the logistic curve relating premenstrual syndrome and daily consumption of caffeine-containing beverages or daily total fluid intake.[21]

We assessed the magnitude of confounding of the premenstrual syndrome prevalence odds ratio by either daily consumption of caffeine-containing beverages or by daily total fluid consumption (depending upon which of these two variables was the variable of interest) by stratifying the data into categories of the potential confounding factor and obtaining an estimate for a uniform prevalence odds ratio by the method of maximum likelihood.[22] The categories used were identical to the categories formed by empirically determining the intervals over which the premenstrual syndrome prevalence odds ratio was uniform.

The level of severity of premenstrual syndrome was determined by each participant in response to a question asking her to assess the overall severity of her symptoms. In addition, a "PMS score" was calculated for each woman. This score was equal to the sum of each respondent's rating of severity for each in the list of 10 symptoms plus the "other" symptoms category, as contained in the questionnaire. A score of one was assigned to each symptom rated mild, a score of two was assigned to each moderate symptom, and a score of three was assigned to each severe symptom. The range of possible PMS scores, therefore, was 0 (no premenstrual symptoms) to 33 (11 severe symptoms).

Results

Prevalence of Premenstrual Symptoms and Types of Beverages Consumed

Six-hundred-and-sixteen (73 percent) of the 841 respondents reported experiencing at least one premenstrual symptom, and 603 (72 percent) reported consuming at least one cup of a caffeine-containing beverage each day. For all types of beverages consumed, a total of 7,048 cups of fluid were reported to be consumed each day: 39 percent water, 20 percent caffeine-containing soda, 12 percent fruit juice, 11 percent milk, 6 percent caffeine-containing coffee, 6 percent caffeine-free soda, 3 percent hot chocolate, 2 percent each caffeine-containing tea and herbal tea, and less than 1 percent each decaffeinated coffee and grain beverages: other beverages accounted for less than 1 percent of the total cups consumed. Seventy-one percent of the total volume of caffeine-containing beverage consumed was soda, 21 percent was coffee, and 8 percent was tea.

Consumption of Caffeine-containing Beverages

The overall prevalence odds ratio for daily consumption of one to 10 caffeine-containing beverages among women who reported experiencing at least one premenstrual symptom compared with women who reported no premenstrual symptoms was 1.5 (90% confidence interval = 1.1, 2.0). This effect was restricted primarily to women whose PMS scores equaled 16 through 31 (the highest score observed).

For the 399 women with PMS scores between 1 and 15 (median score = 9), the prevalence odds ratio for daily consumption of any caffeine-containing beverages (one to ten cups per day) was 1.3 (90% CI = 0.9, 1.7). This point estimate remained unchanged when controlled for daily total fluid consumption. The estimates for one to five cups per day, and for six to 10 cups per day, were similar (1.2 and 1.1, respectively) when daily total fluid consumption was controlled (Table 1).

Among women with PMS scores from 1 to 15, 61 percent rated the overall severity of their PMS symptoms "mild" while only 2 percent rated their symptoms "severe."

Table 2 shows the prevalence odds ratios of premenstrual syndrome for consumption of caffeine-containing beverages among the 217 women whose PMS scores equaled 16 through 31 (median score = 19). For these women, the overall prevalence odds ratio (one to 10 cups of caffeine-containing beverages per day relative to no cups) was 2.0 (90% CI = 1.4, 2.9). A steadily increasing prevalence odds ratio was observed for increasing amounts of daily consumption of caffeine-containing beverages, ranging from 1.3 for one cup per day to 7.0 for eight to 10 cups per day. All of the estimated prevalence odds ratios, except the estimate for one cup per day, were slightly reduced when daily total fluid consumption was controlled (Table 2).

The p-value of the test for trend between premenstrual syndrome and daily cups of caffeine-containing beverages

TABLE 1—Prevalence Odds Ratios of Premenstrual Syndrome According to Daily Consumption of Caffeine-containing Beverage Consumption among the 399 Women Whose PMS Scores Equaled 1 through 15

consumed was <0.001. The slope of the logistic curve relating premenstrual syndrome and daily consumption of caffeine-containing beverages (without control for total fluid intake) was 0.22 (standard error = 0.047). The slope of the logistic curve relating premenstrual syndrome and caffeine-containing beverage consumption, controlling for daily total fluid intake, was reduced to 0.18 (standard error = 0.046); thus, each additional daily cup of caffeine-containing beverage was associated with a 20 percent increase in the prevalence of premenstrual syndrome ($e \cdot 18 = 1.2$).

Among women with PMS scores from 16 to 31, 12 percent rated the overall severity of her symptoms "mild" while 18 percent rated her symptoms "severe."

Types of Caffeine-containing Beverages

Table 3 shows the prevalence odds ratios of premenstrual syndrome among women with PMS scores equal to 16 through 31 who consumed either caffeine-containing soda or caffeine-containing tea or coffee on a daily basis. The data show that both caffeine-containing soda and caffeine-containing tea/coffee were associated with an increase in the prevalence of premenstrual symptoms, and that the effect was higher, per amount of exposure, for consumers of tea/coffee than for soda consumers over the range of consumption studied (0 to 8 cups of soda, and 0 to 3 cups of tea/coffee). There were too few data on which to base effect estimates for larger amounts of consumption.

1.0	1.4 (0.6, 3.3)	5.3 (2.3, 12.2)

*Prevalence Odds Ratio, Relative to 0 Cups per Day (90% Confidence Interval).
**Based on the 176 cases who consumed caffeine-containing soda on a daily basis but who did not consume caffeine-containing tea or coffee, and on 121 cases who consumed no caffeine-containing beverages.
***Based on the 41 cases who consumed caffeine-containing tea or coffee on a daily basis but who did not consume caffeine-containing soda, and on 121 cases who consumed no caffeine-containing beverages.

Total Fluid Intake

The overall prevalence odds ratio for daily consumption of six to 19 cups of fluid, relative to daily consumption of two to five cups, among women who reported experiencing at least one premenstrual symptom compared with women who reported no symptoms was 1.7 (90% CI = 1.0, 3.0). The prevalence odds ratios for women with PMS scores between 1 and 15 (less severe symptoms) were 1.2 (0.6, 2.4), 1.7 (0.9, 3.3), and 2.1 (1.0, 4.5) for 6–7 cups per day, 8 to 10 cups per day, and 11–19 cups per day, respectively.

Table 4 shows the prevalence odds ratios of premenstrual syndrome for total fluid intake, with and without control for daily consumption of caffeine-containing beverages among the 217 women with PMS scores between 16 and 31 (the same subset of women referred to in Table 2). For these women, the overall prevalence odds ratio (six to 19 cups of fluid consumed per day relative to two to five cups consumed per day) was 1.7 (90% CI = 1.1, 2.7). A steadily increasing prevalence odds ratio was observed for increasing amounts of daily total fluid intake, although the size of the increase was small from six or seven to 11–12 cups of fluid per day. The prevalence odds ratio estimates were reduced somewhat when daily consumption of caffeine-containing beverages was controlled. In both sets of estimates, the only large effects observed were among women consuming between 13 and 19 cups of fluid each day.

The p-values associated with the overall trend between premenstrual syndrome and daily total fluid intake were <0.001 and 0.01 without and with control for daily consumption of caffeine-containing beverages, respectively. The corresponding slopes of the logistic curves were 0.091 (standard error = 0.027) and 0.065 (standard error = 0.026).

Discussion

We found a strong association between consumption of caffeine-containing beverages and the prevalence of premenstrual symptoms which was not explained by daily total fluid consumption. The effects for women with PMS scores between 16 and 31 (women with more severe symptoms) were highly dose-dependent, and were present both among women whose source of caffeine was soda and to a stronger extent (on a per cup basis) among women whose source of caffeine was tea and/or coffee. The relation between daily total fluid consumption and premenstrual symptoms, both with and without control for daily consumption of caffeine-

TABLE 4—Prevalence Odds Ratios of Premenstrual Syndrome According to Daily Total Fluid Consumption with and without Controlling for Daily Consumption of Caffeine-containing Beverages among the 217 Women Whose PMS Scores Equaled 16 through 31

containing beverages, was more moderate (over the ranges of values studied) than was the relation for daily consumption of caffeine-containing beverages. The relation between premenstrual symptoms and daily total fluid intake appeared to be dose-dependent, at least when the highest level of intake (13–19 cups per day) was taken into account. The fact that the estimated effects for daily total fluid intake were similar for women with PMS scores between one and 15 (mild symptoms), and for women with PMS scores between 16 and 31 (more severe symptoms), however, seems difficult to reconcile with a causal interpretation of the observed effects.

One possible source of error in this study warrants discussion. We used a self-administered questionnaire to collect information about the presence and severity of premenstrual symptoms. Although a definition of premenstrual syndrome was included in the questionnaire, it may be that some women confused premenstrual with menstrual symptoms or otherwise misinterpreted the meaning of "premenstrual symptoms," and responded accordingly. To evaluate this possibility, 51 study participants volunteered to keep a three-month daily record of symptoms, and to record the first and last days of their menstrual periods. (These women also maintained a daily record of certain dietary factors, exercise history, and stressful life events which may have affected daily symptoms such as anxiety or depression.) These women were told that the purpose of the daily diary was to obtain more detailed information about symptoms throughout the menstrual cycle than was possible using a one-time mail questionnaire. Forty-three (84 percent) of the volunteers completed at least two months of the daily diary. Of these women, 32 (74 percent) completed all three months. One of us (AMR), blinded with respect to the volunteers' responses on the mail questionnaire, rated the severity of premenstrual symptoms (no symptoms, mild, or moderate/severe) for each of the 43 subjects who completed at least two months of the diary, and then compared these ratings to the PMS scores as determined from each woman's mail questionnaire. Overall, 60 percent (26/43) of the ratings and PMS scores matched; that is, the blind assessment of severity, which was based on the actual symptoms recorded in the daily diaries, corresponded to the assessment of PMS severity as summarized in the PMS score (0 = no PMS, 1–15 = mild, 16 or higher = moderate/severe). The majority of the misclassification (11 of 17 misclassified cases) occurred among women who were rated as not having premenstrual syndrome but whose PMS scores equaled one to 15 (mild). Considerably less misclassification occurred between other categories of PMS severity.

The effects of such misclassification, if generalizable to the other study participants, would be to reduce somewhat the size of the observed associations between consumption of caffeine-containing beverages or total fluid intake and PMS among women with PMS scores of 16 or higher, and to substantially reduce the size of the observed associations between consumption of caffeine-containing beverages or total fluid intake and PMS among women with scores of one to 15. The lack of a strong, observed association between consumption of caffeine-containing beverages and PMS among women with PMS scores of one to 15 may be attributable in large part to the inclusion of women who do not regularly experience premenstrual symptoms into this PMS group.

Neither observation bias nor selection bias would seem to be a potentially large source of error in the present study because data from both women who experience premenstrual symptoms and women who do not experience these symptoms were collected in the same manner using identical mail questionnaires; the questionnaire contained an equal number of questions about menstrual health as it contained about premenstrual health; the study hypothesis was not disclosed to the study participants nor is the hypothesis generally well-known or accepted to be true among the population studied; and none of the 51 study participants who volunteered to keep daily records of symptoms (with whom there was bi-weekly personal contact) indicated that she suspected the specific nature of the study hypotheses.

The observed associations between premenstrual symptoms and daily consumption of caffeine-containing beverages theoretically could reflect some uncontrolled third factor but any such factor would have to be present among both caffeine-containing soda consumers and among caffeine-containing tea/coffee consumers, would have to vary jointly with the amounts of such beverages consumed, and would have to be prevalent among young women in both the United States and the People's Republic of China.[5] Neither alcohol use, cigarette use, exercise habits, oral contraceptive use, nor a diet high in beef or refined sugar products, all putative causes/preventives of premenstrual syndrome, satisfies such criteria. A mechanism involving the depressive action of adenosine on central neurons has been suggested by Phillis for how caffeine might cause premenstrual syndrome.[23]

Theoretically, a definitive evaluation of the effects, if any, of caffeine-containing beverages on premenstrual syndrome would involve a randomized trial. The inherent difficulties in conducting such a trial, however, would be considerable.

It seems worth considering that the etiological factors of premenstrual syndrome may operate anew during each menstrual cycle, making the latent period between exposure to caffeine-containing beverages and the onset of premenstrual syndrome short. If true, any beneficial effects which arise from the elimination of caffeine from the diet should be apparent within a relatively few menstrual cycles. For this reason, and because there are few, if any, known beneficial effects associated with caffeine-containing beverage consumption, women who wish to reduce the severity of their premenstrual symptoms may want to consider eliminating caffeine-containing beverages from their diets and then evaluating any changes in the severity of their symptoms after several months. Such a decision, determined on the basis of each woman's personal history with premenstrual symptoms, should be made with full knowledge that there may be no benefits derived from such abstinence for a particular woman. This is the case, however, for many public health recommendations whose bases reside in population-based (epidemiologic) research.

APPENDIX

Subset of the Questionnaire: Question About Beverage Intake

23. About how many *cups* of each of the following beverages do you drink during a typical *day?* (One "cup" is equal to about eight ounces, or one measuring cupful.)

Water:_____
Fruit juice_____
Milk_____
Caffeine-free soft drink_____
Caffeine-containing soft drink_____
Hot chocolate_____
Decaffeinated coffee_____
Caffeine-containing coffee_____
Herbal tea (non-caffeine-containing tea)_____
Caffeine-containing tea_____
Milk shake, ice cream soda_____
Other beverages (note that alcoholic drinks are listed in question 24)_____

CPHA to Sponsor November 29 Symposium on Proposals for ICD–10

With the implementation of the 10th revision of the *International Classification of Diseases* (ICD–10) scheduled for the first half of this decade, health care providers, policy makers, and others will be able to classify and collect more comprehensive patient data than ever before. ICD–10 represents a complete restructuring of ICD–9–CM, the classification system currently used in the United States to code patient diagnoses in the inpatient hospital setting. Designers of ICD–10 are structuring the new taxonomy so that health care professionals will be able to capture data that will facilitate "cradle to grave" health care analyses.

To address the changes in coding technology that will result with ICD–10, the Commission on Professional and Hospital Activities (CPHA) of Ann Arbor, Michigan is sponsoring a national symposium in Chicago, November 29, 1990. Attendees at the symposium will evaluate the work that has been done thus far on chapter 21 of ICD–10, which deals in large part with ancillary factors, such as social environment or occupational hazards which influence the patient's health status and necessitate contact with health services, both as an inpatient and in the ambulatory setting. Participants from national organizations, speakers who will address specific issues, and a reactor panel all will be featured in the symposium. Health care professionals interested in learning more about the conference or in participating on the reactor panel should contact Marge Zernott, Director of Classification Development at CPHA, tel: (313) 930-7990.

Walking and Serum Cholesterol in Adults

LARRY A. TUCKER, PHD, AND GLENN M. FRIEDMAN, MD

Abstract: We measured the association between walking for exercise and the ratio of total cholesterol/HDL cholesterol in 3,621 adults. After controlling for age, gender, income, body fat, alcohol use, exercise other than walking, and cigarette smoking, adults in the high, moderate, and low duration walking categories were compared to those in the no walking-no exercise category. The relative risk for total/HDL ratios of 5.0 or more were .46 (95% CI = .27, .80), .48 (95% CI = .30, .76), and 1.11 (95% CI = .81, 1.53) respectively. (*Am J Public Health* 1990; 80:1111–1113.)

Introduction

Although hypercholesterolemia is a key risk factor of cardiovascular disease,[1] its determinants, including physiologic, demographic and lifestyle factors, are less well established. Mounting evidence indicates that physical activity fosters favorable levels of serum cholesterol,[2–6] but findings have been inconsistent,[7–13] and many of the investigations have failed to control for the effects of alcohol use, body fat, tobacco use and other factors.

Despite the present-day enthusiasm for walking as a means of promoting health and fitness,[14,15] only two investigations have been conducted to determine the relation between walking and serum cholesterol,[10,16] and they have shown mixed results. Hence, the present study was conducted to assess the relation between walking for exercise and serum cholesterol, particularly the total cholesterol/high density lipoprotein cholesterol (HDL) ratio in 3,621 adult men and women. A secondary purpose was to ascertain the extent to which physiologic, demographic, and lifestyle factors confound the association.

Methods

Subjects

Subjects were employees of over 25 different companies that chose to participate in an ongoing health promotion/disease prevention screening program. Approximately 62 percent of the subjects were female, 85 percent were White, 69 percent were married, and 66 percent reported some college education. Mean age of the sample was 40.0 years (SD = 11.1) and the median gross family income was between $25,000–$30,000.

Approximately 14 percent of the employees elected not to participate in all of the health evaluations leaving a sample of 3,621 adults for the present investigation.

Instrumentation and Procedures

Registered nurses employed by Health Advancement Services, Inc., collected all of the data. Each subject was examined individually and privately for 60 minutes after participating in an orientation and completing an informed consent form. A structured questionnaire was used to collect demographic and lifestyle information. Weekly duration and frequency of walking for exercise was assessed as recommended by Stephens, *et al*,[17] but walking intensity was not measured. Total time spent exercising each week was also measured. A step test, the Kasch 3-minute Pulse Recovery Test,[18] assessed cardiovascular fitness. In the present study, as reported walking duration increased, physical fitness increased showing strong linear (Mantel-Haenszel: $\chi^2 = 48.0$, df = 1, $p = 0.0001$) and general associations ($\chi^2 = 87.5$, df = 18, $p = 0.0001$). Indirect validation of the total exercise time variable was demonstrated previously.[19]

Approximately 10 cc of blood was drawn from each subject and analyzed using the enzymatic method to determine serum cholesterol levels.[20] A Harpenden skinfold caliper was employed to assess subcutaneous fat at three body sites on each subject: for males, thigh, chest, abdomen; for females, iliac crest, triceps, thigh. The sum of the skinfold measurement along with age and gender were used to calculate the total body fat percentage of each subject.[21]

Data Analysis

Subjects were grouped into four categories according to their self-reported, weekly duration of walking for exercise and total exercise time:

- *None*: subjects reporting no weekly walking for exercise nor any regular exercise;
- *Low*: ½–2 hours of weekly walking for exercise;
- *Moderate*: 2½–4 hours of weekly exercise walking;
- *High*: 4½ hrs per week or more of exercise walking.

The total serum cholesterol/HDL ratio was calculated because the total/HDL ratio has greater heart disease predictive utility than the others used individually.[1] A total/HDL ratio of 5.0 or greater was used to signify high risk according to current recommendations.[22]

The relation between weekly walking duration and elevated total cholesterol/HDL ratios was measured by the odds ratio.[23] Subjects who reported no weekly walking for exercise nor any regular physical exercise were used as the reference group. Mantel-Haenszel summary risk estimates[24,25] were employed to control for the potential confounders: age, gender, income, body fat, alcohol use, cigarette smoking, and exercise other than walking. Analysis of covariance (ANCOVA) was used to determine mean total cholesterol, HDL-C and total/HDL cholesterol differences among the walking groups with the potential confounders controlled.

Results

Table 1 shows the relations between the control variables, walking duration, and the total cholesterol/HDL ratio. High walking duration was more common in those who were male, leaner, poorer, nonsmokers or light smokers, not heavy drinkers, those who performed little exercise other than walking, and those in their 20s or above 50 years of age. Those with elevated total/HDL ratios tended to be male,

*"Exercise" included all exercise reported except walking.
[a]"None" (reference group), under the "Hours of Weekly Exercise Walking" heading included adults who did not walk for exercise or perform any other type of regular exercise.

older, fatter, smokers, drinkers, non-exercisers, and not poor.

Table 2 displays the prevalence of elevated total cholesterol/HDL ratios among the adults in the reference and walking categories, and estimated risk for each of the groups before and after adjustment for the potential confounders.

Table 3 shows the mean cholesterol differences among the four walking categories with the potential confounders controlled statistically (ANCOVA).

Discussion

The present findings indicate that adults who walk for exercise 2½–4 hours or more each week tend to have less than one-half the prevalence of elevated total cholesterol/HDL ratios (total/HDL ratio ≥ 5.0) as those who do not walk or exercise regularly.

There are a number of explanations as to why walking duration and the total/HDL ratios appear to be strongly related. High total cholesterol/HDL ratios may reflect problems that lead to decreased exercise-walking. Because subjects with elevated total/HDL ratios tend to be more obese and smoke more than their counterparts[1,26] and because obese adults and those who smoke tend to walk less than non-obese and non-smokers (findings of present study), adults with elevated ratios may choose not to walk as much as others. Elevated total cholesterol/HDL ratios and exercise-walking each may be caused by other common factors.

TABLE 2—Estimated Risk of Elevated Total/HDL Ratio by Weekly Walking Duration

Weekly Walking Duration	Variable Controlled	Elevated Total/HDL Ratio[a]			
		N	%	RR_{mh}	95% CI
None (n = 1,970)	none	583	29.6	1.00	—
1/2–2 hrs (n = 972)	none	233	24.0	0.75	0.63,0.89
	age, gender, ses, fat, alcohol, smoking, other exercise[b]			1.11	0.81,1.53
2 1/2–4 hrs (n = 406)	none	90	22.2	0.68	0.53,0.87
	age, gender, ses, fat, alcohol, smoking, other exercise[b]			0.48	0.30,0.76
4 1/2 hrs + (n = 273)	none	73	26.7	0.87	0.65,1.15
	age, gender, ses, fat, alcohol, smoking, other exercise[b]			0.46	0.27,0.80

NOTE: Subjects who reported no regular exercise walking or other exercise were used as the reference group.
[a]Elevated Total/HDL ratios were defined as those ratios ≥ 5.0.
[b]Other exercise included all exercise reported other than walking.

TABLE 3—Adjusted Mean Differences in Cholesterol among the Walking Groups

	Weekly Walking Duration							
	None		Low		Moderate		High	
Variable	Mean	SD	Mean	SD	Mean	SD	Mean	SD
Total/HDL Ratio	4.81	1.6	4.70	1.4	4.49	1.3	4.53	1.6
Total-C (mmol/L)	5.34	1.1	5.28	1.0	5.19	1.1	5.19	1.1
HDL-C (mmol/L)	1.18	0.3	1.20	0.3	1.22	0.3	1.22	0.3

Means were adjusted for differences in age, gender, income, body fat, alcohol use, exercise other than walking, and cigarette smoking.

With the moderate and high duration walking groups combined and the covariates controlled, the following mean differences resulted (mmol/L):

Total/HDL ratio: None (M = 4.86) Moderate + High (M = 4.53), difference (.33); 95% confidence limits of the difference (.18, .46), $p < .05$

Total-C: None (M = 5.33) Moderate + High (M = 5.14), difference (0.19); 95% confidence limits of the difference (0.08, 0.29), $p < .05$

HDL-C: None (M = 1.17) Moderate + High (M = 1.21), difference (0.04); 95% confidence limits of the difference (0.01, 0.06), $p < .05$

Other potential confounders, particularly diet, could account for the inverse association between walking duration and elevated total/HDL ratios since research suggests that exercisers may consume different diets than non-exercisers,[27] and diet may be related to serum cholesterol levels.[1]

Finally, desirable total/HDL ratios may, in fact, result from moderate to high levels of exercise walking. Numerous studies confirm a connection between other types of aerobic exercise, besides walking, and favorable levels of serum cholesterol.[2–6]

Because subjects in the present study had relatively high socioeconomic status and education levels, generalization to poorer, less educated groups will necessitate further research.

Given the correlational design of this study, cause-and-effect conclusions are not warranted. However, if a causal relation is assumed, then at least 2½ to 4 hours of exercise walking per week should be practiced for protection against elevated total/HDL ratios. In the present study, ½ to 2 hours of weekly walking for exercise was not associated with decreased risk of high total/HDL ratios.

Abstinence from Smoking and Expired-Air Carbon Monoxide Levels: Lactose Intolerance as a Possible Source of Error

Ann D. McNeill, PhD, Lesley A. Owen, PhD, Michael Belcher, RMN, Gay Sutherland, MPhil, and Simon Fleming, MSc

Abstract: We investigated a possible source of contamination of expired-air carbon monoxide (CO) readings on CO monitors from raised expired-air hydrogen (H_2) levels, namely lactose intolerance, the norm in certain ethnic groups. A significant correlation between expired-air CO and H_2 readings was observed in four non-smoking lactose maldigesters. (*Am J Public Health* 1990; 80:1114–1115.)

Introduction

Expired-air carbon monoxide (CO) measurement is a simple and cheap method of validating non-smoking status in ex-smokers.[1] While falling short of the specificity and sensitivity of cotinine measures, it is the preferred method in a wide range of field settings.[2] Its application takes on particular value in the light of the increasing use of nicotine replacement strategies in smoking cessation. It is important that this test be valid if the success rates of smoking cessation interventions are to be correctly estimated and individuals spared needless embarrassment should they be suspected of not telling the truth about their smoking status.

We investigated a possible source of false positives in expired-air CO readings.

Method and Results

Bedfont EC50 and EC50 micro smokerlyzer portable CO monitors are the most popular means of measuring expired-air CO in smoking clinics in the United Kingdom[3] and are also used in the United States. The non-smoking/smoking cut-off CO value most commonly used is 10 ppm.[2] A non-smoking member of our staff was surprised to find a level of 36 ppm expired-air CO after routinely blowing into such a monitor as a demonstration of its use. This raised level was obtained with other Bedfont CO monitors and was not attributable to raised ambient CO.

Expired-air CO levels after 20 seconds breath-holding are in approximate equilibrium with the concentration of carboxyhaemoglobin in the blood.[1] However, in this case, carboxyhaemoglobin levels were normal (1.0 percent) indicating that expired-air CO levels were not raised and that the CO monitor must have been picking up another gas.

The instruction manual for these monitors indicated that they are specially constructed to be insensitive to interferences from hydrogen (H_2), alcohol, and other organic species.[4] As alcohol was eliminated as a possible source of interference, H_2 levels were investigated. The technical specification for the CO monitors indicates that 20 ppm H_2 would give less than a 4 ppm reading.[4]

Raised H_2 levels in humans can arise from several causes, such as lactose intolerance, excessive bacteria in the small intestine and variations in transit time through the small intestine.[5] Recent studies also indicate that breath H_2 excretion increases between three and seven hours after normal subjects have ingested flours derived from whole or refined wheat, oats, corn, potatoes or baked beans.[6]

Monitoring the subject's CO levels throughout the day revealed a strong diurnal pattern which was possibly related to food intake (breath hydrogen tends to be higher after waking).[6] Further investigation revealed that this subject was lactose intolerant. A Bedfont EC60 H_2 monitor which measures the H_2 content of expired air, confirmed that H_2 levels were raised and mirrored the apparent CO levels throughout a typical working day (see Figure 1). This suggested that the CO reading was being contaminated by raised H_2 levels.

The relation between expired-air CO and H_2 levels was further investigated using lactose tolerance tests.[7] A significant correlation between the expired-air CO and H_2 readings was observed in this subject and in an additional three

This paper, submitted to the Journal August 7, 1989, was revised and accepted for publication December 14, 1989.

© 1990 American Journal of Public Health 0090-0036/90$1.50

non-smokers who were known to be lactose maldigesters ($r = 0.99$, $r = 0.95$, $r = 0.97$, and $r = 0.75$; $n = 6$ for each subject; range for CO values = 3 to 34 ppm; range for H_2 levels = 2 to 183 ppm). A regression analysis was carried out using the CO and H_2 values to estimate the level of hydrogen at which a CO reading of 10 ppm would be obtained. A linear trend was fitted across time and yielded a non-significant time-subject interaction and between-subject effect. An expired-air H_2 level of 38.91 ppm would be sufficient to register 10 ppm on a CO monitor (2.5 percent of individuals with levels of 42.07 would register less than 10 ppm, 2.5 percent of individuals with levels of 35.75 would register above 10 ppm). In lactose maldigesters a CO level of 10 ppm would therefore be achieved by consuming, for example, 350 ml or approximately two small glasses of milk.

Discussion

Despite the methodological limitations imposed by the small sample size, the strong patterns observed indicate that there may be cases where individuals classified as smokers on the basis of CO validation have a condition which results in raised expired-air H_2 levels. The proportion of the population who would fall into this category is unknown. As stated earlier, one of the causes of raised H_2 levels is lactose intolerance, which is thought to have a strong hereditary component: a recent estimate of primary lactose intolerance in the UK is given as 6 percent.[8] However, it can also be acquired following diseases which damage the small intestinal villi, for example, giardiasis, coeliac disease, tropical sprue, chronic alcoholism, rotavirus infections in children, and cholera.[7,8] Furthermore, not all lactose intolerant individuals are aware of their condition[9] and some can tolerate moderate quantities of milk, possibly as a result of acquired tolerance to the symptoms.[7]

The likelihood of middle-class Caucasians having raised H_2 levels due to lactose intolerance which could contaminate CO levels may be minimal. However, in certain ethnic groups the prevalence of lactose intolerance is much higher, for example, Jews,[9] American Blacks (among whom the figure is 75 percent), and certain African and Oriental races where it approaches 100 percent.[8] It would be counter-productive if a greater proportion of minority groups, when attempting smoking cessation, were to be wrongly labeled. Among such groups, CO validation may need to be supplemented by cotinine, or if nicotine replacement is being used, by carboxyhaemoglobin analysis. It would not be sufficient when performing the expired-air CO test to ask when the subject last consumed a dairy product as there are considerable inter and intraindividual differences in rates of absorption.[6]

ACKNOWLEDGMENTS

We are very grateful to Cyril Vesey for analyzing the carboxyhaemoglobin samples and Dr. Ian Forgacs for his useful discussions and support. Financial support was provided by the Medical Research Council.

A Population-Based Descriptive Study of Housefire Deaths in North Carolina

MICHAEL J. PATETTA, MA, AND THOMAS B. COLE, MD, MPH

Abstract: We report a population-based study of housefire deaths in North Carolina in 1985 using data obtained from fire investigators and the North Carolina medical examiner system. The crude death rate was 3.2 per 100,000 population; age-specific death rates were highest for ages 75–84 years. Death rates for Whites were one-third as high as death rates for other races. Of those decedents tested for alcohol, 56 percent had blood alcohol levels ≥ 22 mmol/L. Most fatal fires were caused by heating units or cigarettes. (*Am J Public Health* 1990; 80:1116–1117.)

Introduction

Three-fourths of the 5,000 fire and burn deaths that occur annually in the United States are caused by housefires.[1,2] In 1984, the US housefire death rate[1] was 1.9 per 100,000 population. However, in the South the rate[1] was 2.5 per 100,000, and in the Southeast in recent years rates have been in the range of 3.05–5.14 per 100,000.[2]

Studies of housefire mortality for the Southeast have found that most deaths occur in heating-related fires, whereas smoking-related fires are responsible for most of the deaths in other parts of the country.[3] There is some evidence that the higher death rate for the Southeast may be attributable to a lower prevalence of smoke detectors and a greater use of portable heating equipment compared with other regions.[4,5]

To describe the epidemiology of housefire deaths in a Southeastern state, we conducted a statewide, population-based study of housefire deaths in North Carolina.

Methods

Records of all housefire deaths in North Carolina in 1985 were obtained from the Office of the Chief Medical Examiner. State law mandates reporting of all fatal injuries to a medical examiner. County medical examiners complete a report (which includes toxicologic information, reports of death scene visits and interviews with witnesses, autopsy records, and other relevant data) for each investigated death for review by a forensic pathologist.

Information about the causes of the housefires was requested from the local fire marshalls or county sheriffs, and responses were received for 70 percent of housefire deaths. The causes of the housefires were documented in Medical Examiner Reports or State Bureau of Investigation Reports for an additional 22 percent of deaths.

Rates and proportions were calculated from pooled data. Housefire death rates are expressed per 100,000 population, but these rates are approximate because some decedents were not North Carolina residents and information was not obtained for North Carolina residents who died out of state.

Results

In 1985, 159 housefires resulted in 200 deaths, accounting for 75 percent of all North Carolina deaths from fire and burns. All but three decedents were North Carolina residents. The crude death rate from housefires was 3.2 per 100,000 population. Death rates were highest (8.8/100,000) for persons ages 75–84 years (Table 1) and for persons other than White (7.1) (Table 2).

Of 157 persons who died at the scene of the fire and were tested for carboxyhemoglobin, 131 (83 percent) were reported by a medical examiner to have died of carbon monoxide poisoning and 26 from burns. Of the 26 not tested, seven (27 percent) were reported to have died of carbon monoxide poisoning and 19 from burns.

Of 160 decedents ≥ 15 years of age, 56 percent of the 130 tested for alcohol had blood alcohol levels ≥ 22 mmol/L (legally impaired under North Carolina driving laws). Of those tested, 85 percent who died in cooking-related housefires, 60 percent who died in smoking-related housefires, and 39 percent who died in heating-related housefires had blood alcohol levels ≥ 22 mmol/L.

Most of the victims (59 percent) died when single-family houses burned, although 76 percent of the North Carolina population lived in single-family houses according to the 1980 census. Although only 9 percent of the North Carolina population lived in mobile homes in 1980, 19 percent died in mobile home fires. Smoke detector information was provided for 72 fatal housefires. Of the 109 deaths in these housefires, 94 percent occurred in dwellings without smoke detectors.

More deaths resulted from housefires caused by heating units (33 percent) than from any other cause (Table 3). Of the 60 heating-related housefire deaths, 20 percent were associated with the use of flammable liquids and 25 percent with the ignition of furniture or furnishings. Woodstoves caused the fires that resulted in 37 percent of heating-related deaths, and kerosene heaters were responsible for an additional 20 percent.

Total	200	3.2

*Death rates per 100,000 population are approximate because all instate deaths were counted regardless of the state of residence.

**With the exception of one American Indian male, all deceased persons of other races were Black. Census data for 1985 do not provide population estimates for Blacks and American Indians.

TABLE 3—Housefire Deaths by Cause* of Fire, North Carolina, 1985

Cause of Fire	Number (%) of Deaths
Heating	60 (33)
Smoking	47 (26)
Cooking	16 (9)
Electrical	15 (8)
Arson	10 (6)
Open Flame	9 (5)
Children Playing	9 (5)
Natural	1 (1)
Undetermined	16 (8)
Total**	183 (101)

*Causes are assigned according to the hierarchy used by the National Fire Data Center of the Federal Emergency Management Agency, so that the number of deaths in each sucessive cause is exclusive of all previously listed causes. For 17 deaths, cause of fire information was not provided by fire investigators.

**Total is > 100% due to rounding.

The second most common cause of housefire deaths was smoking (26 percent). Of the 47 smoking-related housefire deaths, 89 percent occurred in fires caused by the ignition of furniture.

Discussion

Only 16 persons who died in 1985 as result of housefires in North Carolina left the scene of the fire alive. Therefore efforts to improve the emergency treatment and transport of persons injured in housefires could prevent at most 8 percent of housefire deaths. To prevent housefire deaths, fires must be prevented or escaped.

Assuming that the proportion of the North Carolina population living in mobile homes did not change from 1980 to 1985, mobile home dwellers are 2.7 times as likely to die in housefires as persons who live in single-family detached homes. A similar risk was found in New Mexico.[6]

We estimate that the lethal[7–10] combination of alcohol and cigarettes resulted in at least one-fourth of the deaths reported in this study. The proportion of fatally injured persons tested who were impaired with alcohol was greater for housefires (56 percent) than that for any other cause of unintentional injury in North Carolina. The use of fire-safe cigarettes[11] may be the most effective way to prevent deaths associated with drinking and smoking.[2,6]

Escape from housefires is facilitated by early warning, which can be provided by smoke detectors.[8,12] The risk of death from housefire is estimated to be 2.5 times greater for persons who live in homes without smoke detectors.[13] Unfortunately, persons who are very young, very old, or very drunk may not be able to respond to an alarm.[11,13–15] From our data we estimate that these groups accounted for over half of the deaths.

Our study indicates that the risk of housefire death is likely to be multifactorial, with ignition source, type of dwelling, and behavior each playing important roles.

ACKNOWLEDGMENTS

We would like to thank the Fire and Rescue Service Division of the North Carolina Department of Insurance; the North Carolina State Bureau of Investigation; and the Division of Post-Mortem Medicolegal Examination of the North Carolina Department of Environment, Health, and Natural Resources for their guidance, their data, and their enthusiastic support.

Estimating the Full Cost of Workplace Injuries

MICHAEL T. FRENCH, PHD

Abstract: While many studies estimate medical costs and lost wages from workplace injuries, few have estimated pain and suffering costs. This study develops a wage-risk model for railroad workers and estimates the total cost of on-the-job injuries. On average, the total cost of an on-the-job injury to a railroad worker in 1980 was between $19,500 and $22,500. These estimates are substantially higher than the sum of medical costs plus lost wages. (*Am J Public Health* 1990; 80:1118–1119.)

Introduction

Workplace injuries impose a variety of costs on injured workers. The most frequently estimated costs are expenditures for medical services and wages lost from missed work. But injured workers also bear other costs such as pain and suffering.

Economists use several methods to estimate the cost of workplace injuries. The conventional approach is the cost-of-illness method.[1–5] In simple form, the cost-of-illness method estimates the cost of injury as the sum of medical-related expenditures plus lost wages. The strengths of the cost-of-illness method are that it uses accessible data on medical expenditures and personal earnings, and it is easy to apply. The main weakness of the cost-of-illness method is that it neglects important components of the total cost of workplace injury.

Recently, economists have developed methods to estimate the cost of workplace injuries based on individuals' willingness to pay to reduce injury risks. If workers perceive and understand the consequences of on-the-job injuries, the willingness-to-pay method captures the full range of costs to individuals.

The willingness-to-pay method is not without limitations, however. If workers underestimate their true exposure to workplace risks and if real or perceived barriers inhibit workers from reacting to risk changes (e.g., long-term labor contracts), then injury cost estimates will be downward biased. In addition, since willingness to pay is influenced by workers' income, *ability* to pay is inseparable from *willingness* to pay. Nevertheless, the willingness-to-pay method represents a major stride toward estimating the full cost of workplace injuries.

Several researchers have used the willingness-to-pay method to estimate the cost of premature death,[6–10] but few have studied nonfatal injuries.[11,12] This paper develops a willingness-to-pay model and estimates the full cost to workers of on-the-job injuries in the railroad industry.

Methods

Generally, workers' wages depend on demographic characteristics of the workers (e.g., age, education, marital status, and region of residence), characteristics of the job (e.g., blue collar, white collar, skilled, or unskilled), and the riskiness of the job. Job risk can be measured as the number of injuries per million worker-hours. Using multivariate regression analysis applied to data from a sample of workers, researchers can estimate the importance of each variable in determining workers' wages. In particular, the analysis shows how much workers must be paid to get them to accept additional workplace risk, other things held equal. The amount workers must be paid to accept additional risk is called the "compensating wage differential."

The compensating wage differential is at the heart of the willingness-to-pay method for estimating total cost imposed on workers by on-the-job injuries. For example, suppose the regression analysis shows that the compensating wage differential is $0.50, calculated on weekly wages. In other words, on average, workers in the sample are willing to accept a $0.50 reduction in weekly wages ($26 per year) for a one-unit decrease in the workplace injury rate. If the annual probability of workplace injury is 0.004, then four in 1,000 workers are likely to be injured on the job each year. Since on average each individual is willing to accept a $26 reduction in annual wages to reduce the probability of injury to 0.003, or three in 1,000, then the workers' total willingness to pay to avoid one injury is ($26 per worker)(1,000 exposed workers) = $26,000.

This analysis uses wage, demographic, and occupational data from the March 1980 Current Population Survey[13] plus on-the-job injury data from the Federal Railroad Administration[14] and the Association of American Railroads[15] to estimate railroad workers' willingness to pay to reduce workplace risk. The sample includes railroad workers living in the 48 continental states who reported wages, demographic characteristics, personal characteristics, and occupation by Census Bureau categories. Discarding records with missing data and records for workers who had more than one employer in 1980 left a sample of 460 railroad workers. Table 1 lists all variables used in the regression model along with sample means and standard deviations.

TABLE 1—Variable Means and Standard Deviations (N = 460)

Results

I estimated several different wage-risk regression models. Table 2 gives a complete set of parameter estimates and regression statistics from the linear and log-linear specifications. Most coefficients have plausible signs and are statistically different from zero at the 0.05 or higher level of significance.

On average, the estimated annual compensating wage differential for railroad workers is 0.0021 (the regression coefficient for the risk variable from the log-linear specification) multiplied by $437 (the average weekly wage for workers in the sample), multiplied by 49 (the average number of weeks worked per year), which yields a value of $45. To compute a total willingness-to-pay estimate, I multiply the compensating differential estimate ($45) by the average number of workers affected by the injury risk [500 workers = (1 million worker-hours/2,000 hours)], yielding an estimate of $22,500 per injury. Using the linear specification, I estimate railroad workers' total willingness to pay to reduce the risk of workplace injury at $19,500 per injury. All other estimates from different specifications of the regression model fall in the range of $19,500 to $22,500.

Discussion

In 1980, the average on-the-job injury in the railroad industry resulted in 16 days away from work. If workers received no compensation for lost wages and if injured workers spent all 16 days in the hospital—which are clearly overstatements—then the cost-of-illness method estimates the average cost of an injury to an injured worker at only $5,318 ($245 per day for hospital care and $437 per week in lost wages).

Willingness-to-pay estimates from the wage-risk model presented in this paper indicate that, on average, railroad industry employees faced an expected cost of between $19,500 and $22,500 per injury. These estimates are considerably larger than the sum of medical costs and lost wages because they include the cost of pain and suffering. Comparing cost-of-illness and willingness-to-pay estimates suggests that the *avoided* cost of pain and suffering is a substantial component of the total value of workplace safety for railroad workers and that conventional cost-of-illness estimates grossly underestimate the full cost of these injuries.

Perforating Eye Injury in Allegheny County, Pennsylvania

DEBORAH LANDEN, MD, MPH, DAVID BAKER, MD, MPH, RONALD LAPORTE, PHD, AND RICHARD A. THOFT, MD

Abstract: From 1980 through 1986, acute perforating eye injury (ICD codes 871.0–871.9) was diagnosed in 345 residents of Allegheny County, Pennsylvania. The mean incidence rate was 3.49 per 100,000 person years. There was no significant change in incidence over the seven-year period. The largest number of injuries occurred among individuals working with tools, of which 47 percent were occupational. Males had a 6.5-fold risk of injury relative to females. Blacks had a risk of 2.2 times that of Whites, mainly due to an excess of assaultive injuries. Individuals who had had recent ocular surgery accounted for 4.6 percent of cases overall, and for 31.6 percent of cases in those over age 60. (*Am J Public Health* 1990; 80:1120–1122.)

Introduction

Eye injuries are a major cause of visual impairment. They are the leading cause of monocular blindness in the United States, and account for 7 percent of bilateral blindness in the 20–64 year age group.[4]

While several population-based studies of eye injuries have been published, they include predominantly minor injuries which are unlikely to lead to loss of vision.[1–6] Perforating eye injuries threaten vision and can be expected to result in hospitalization at the time of occurrence. Two previous hospital record studies of eye injuries in defined populations have included a report of the incidence of perforating eye injuries. Karlson and Klein reported an incidence of ocular lacerations of two per 100,000 in Dane County, Wisconsin in 1979.[3] Tielsh, *et al*, reported an incidence of open wounds of the eyeball of 3.81/100,000 in Maryland during the years 1979 through 1986.[6]

Only one previous study has reported both incidence rates and risk factors for perforating eye injuries. Blomdahl and Norrell[7] studied perforating eye injuries in the population of Stockholm through review of hospital records and interviews of patients identified as cases. They reported an incidence of 60.6 per million population among men and 11.8 per million among women during the period 1974–79. The highest incidence was in the 10–19 years age group. The most frequent circumstance of injury was paid work, followed by play or sport, domestic work, assault, and traffic accidents. Metal and glass fragments were the most common perforating objects, followed by nails and knives.

We describe the epidemiology of perforating eye injury in Allegheny County, Pennsylvania during the years 1980 through 1986.

Methods

Inpatient records were reviewed at the 24 hospitals in Allegheny County and surrounding areas which serve Allegheny County residents. Cases were defined as any Allegheny County resident discharged from one of the listed hospitals with a primary or secondary diagnosis of perforating eye injury (ICD codes 871.0–871.9).

Demographic information, as well as address at the time of admission, the type of injury incurred, and surgical procedure performed, if any, were abstracted from the records. A brief description of the circumstances surrounding each injury was compiled; information was available for 97 percent of cases. E-codes from the record were not used. Cases included were only those with a first time admission for that diagnosis. Cases seen at more than one hospital for the incident injury (e.g. a community and a tertiary care hospital) were counted only once.

Two hospitals refused to allow review of their medical records. However, they provided a count of cases meeting our ICD code criteria, although no information as to whether the case was an Allegheny County resident. From this information, we estimate that we missed three cases at most from these hospitals.

Population data for Allegheny County were obtained from the Pennsylvania State Data Center. For 1980, these data were from the national census. For other years, estimates developed by the State Data Center by sampling were employed. Rates for each year were age standardized against the 1980 Allegheny County population; 95 percent confidence limits for all rates were calculated.[8] Taylor series confidence intervals were constructed for all measures of relative risk.[9]

In order to assess the effect of socioeconomic status on risk of injury, census tract of residence was determined from the Cole's directory for a random sample of 150 cases, stratified by race.[10] Mean income was determined for census tract of residence from 1980 census data.[11]

Results

Three hundred forty-five Allegheny County residents sustained perforating eye injuries during the years 1980 through 1986, for a mean incidence rate of 3.49 per 100,000

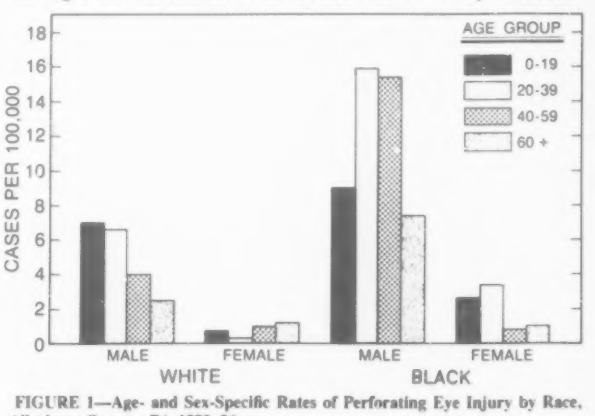

FIGURE 1—Age- and Sex-Specific Rates of Perforating Eye Injury by Race, Allegheny County, PA 1980–86

person years. Annual incidence rates were stable over the seven-year period. Mean incidence rates for the seven-year period, specific for age, race and sex, are shown in Figure 1.

There was only a slight difference in incidence between Whites and Blacks for those under age 20. For those over age 20, the incidence in Whites was reduced, while for Blacks it increased, reaching a peak among those ages 20–59, and then declined in those over age 60 (Table 1). Assaultive injuries were the major contributor to the increased incidence in Blacks (Table 2). When assaultive injuries were excluded, there was no difference in rates between the racial groups for those ages 20–39, although an excess of injuries was still seen among Blacks over age 40.

Injuries to males occurred at a rate 6.6 times that of females, with excess risk for males in all age groups (Table 1) and all categories of cause (Table 2). When occupational injuries were excluded, the relative risk for males compared to females remained elevated at 5.4.

Circumstances of injury are presented in Table 2. The most frequent circumstance of injury, accounting for 23 percent of cases, was work with tools; 47 percent of injuries in this category were occupational. Most injuries occurred when bits of metal, wood, or other material broke off and were propelled into the eye, or when a hammered nail recoiled. However, the tool itself was the cause of injury in four of 11 cases occurring during car repair. In contrast, the tool itself caused injury in only one out of 68 cases not associated with car repair. Five out of 36 occupational injuries occurred when a particle was propelled by another person's work or by machinery in the workplace.

Of recreational activity and childplay injuries, 23 percent were due to BBs.

Minor trauma (e.g. "bumped eye") to individuals with a history of opthalmologic surgery was responsible for 3.2 percent of injuries. We separately analyzed all injuries which had occurred within three months of ocular surgery, whether due to minor or more significant trauma. These injuries accounted for 4.6 percent of cases overall. Among those over age 60, 31.6 percent of all injuries had occurred within three months of surgery. In contrast only 1.3 percent of injuries in those under age 60 were associated with recent ocular surgery.

Falls were the circumstance of injury for 6.7 percent of cases. Seven of 23 fall injuries occurred in nonnormal eyes (postsurgical or underlying condition such as Terrien's marginal degeneration).

Seven and a half percent of injuries were sustained in motor vehicle accidents. The hospital record provided little information about the part of the vehicle actually causing the injury.

TABLE 1—Relative Risk of Perforating Eye Injury, Black:White and Male:Female, by Age, Allegheny County, PA 1980–86

Age	RR B/W	(95% CI)	RR M/F	(95% CI)
0–19	1.30	(.82, 2.07)	7.71	(6.68, 8.74)
20–39	2.77	(1.89, 4.07)	11.18	(10, 12.36)
40–59	2.93	(1.64, 5.23)	4.88	(3.21, 6.55)
60+	2.17	(1.09, 3.25)	2.53	(1.25, 3.81)
Total (Age-Adjusted)	2.18	(1.53, 3.09)	6.55	(5.98, 7.12)

Ten percent required enucleation. Thirteen of these 34 cases were due to assault.

Individuals living in census tracts with mean annual incomes below $10,000 had an incidence rate of 7.4 per 100,000 person years, compared to a rate of 3.2 per 100,000 person years for those living in census tracts with mean incomes above $10,000. The relative risk for low income vs high income census tract residence was 2.3, with a 95 percent confidence interval of 1.47, 3.56.

Discussion

Comparison with the Swedish study of perforating eye injuries (6.6 per 100,000 for men and 1.2 for women) shows that our sex-specific incidence rates of 5.7 and 1.5, respectively are quite similar; they also showed no consistent trend over time.

Young males experienced the highest risk of injury in both studies. We found an increased risk among Blacks. However, this excess risk may represent lower socioeconomic status of Blacks. Individuals living in low income census tracts had a higher risk of injury; mean income for Blacks in Allegheny County is substantially lower than that for Whites.[11]

Among individuals working with tools, over half the injuries occurred in nonoccupational settings. In the occupational setting, injuries can be prevented through required eye protection or separation of persons without eye protection from areas in which they might sustain injury. The many injuries which occurred during home and car maintenance and repair are preventable if people become aware of the risk of eye injury in this setting and wear protection. Efforts to increase public awareness of this hazard are indicated.

Many product-associated injuries can be prevented either by modification or elimination of the product. The continuing rate of visual loss due to BB gun injuries is an example.

TABLE 2—Relative Risk of Perforating Eye Injury by Circumstance, Black:White and Male:Female, Allegheny County, PA 1980–86

Circumstance	Cases (%)	RR B/W	(95% CI)	RR M/F	(95% CI)
Work with tools	78 (22.6)	1.03	(.45, 2.34)	38.80	(3.1, 517.2)
Recreation/Childplay	69 (20.0)	1.35	(.59, 3.08)	13.35	(2.54, 71.69)
Assault	47 (13.6)	9.41	(3.11, 28.5)	6.42	(1.35, 30.24)
Motor Vehicle Accident	26 (7.5)	1.03	(.25, 4.26)	12.84	(.90, 194.9)

*explosions, walking into objects, recoiling objects, animal bites and scratches, accidental gunshot wounds.

A surprisingly large number of injuries occurred among those with recent ocular surgery. This should be investigated further, as such cases were responsible for over a third of injuries to those over age 60.

Fatal and Severe Injury: Scooter and Moped Crashes in California, 1985

MICHAEL SALATKA, MPH, SHAKEH ARZEMANIAN, MPH, JESS F. KRAUS, MPH, PHD, AND CRAIG L. ANDERSON, DHSC, MPH

Abstract: Fatal and severe injury crashes for scooters and mopeds in California for 1985 were compared with those for motorcycles during the same year. Scooters had more than twice the injury crash rate of mopeds but one-half the rate of motorcycles. Age of injured drivers and crash patterns for scooters, mopeds, and motorcycles varied significantly. (*Am J Public Health* 1990; 80:1122–1124.)

Introduction

In the past 15 years, the use of mopeds and scooters in the United States has increased markedly[1]; by 1987, there were an estimated 360,000 scooters and 170,000 mopeds in use.[2]

Some information is available on injuries from moped crashes[3–13] but virtually none on injuries involving scooters. Unlike motorcycles, mopeds and most scooters are not designed for traveling long distances or at high speeds and are not legal for use on freeways in California and most other states. We examine fatal and severe injury crashes for operators of mopeds and scooters in California during 1985 and compare their crash rates and other characteristics to those of motorcycles.

Methods

Definition, Criteria, and Crash Data Source

A moped is a two-wheeled, motor-powered bicycle with an automatic transmission and 12- to 17-inch wheels; almost all have an engine displacement of 49 cc or less. As single rider vehicles, they are not designed to carry passengers. Models made before 1981 may have pedals for propulsion.[14–18]

A scooter is a two-wheeled, motor-powered vehicle with an enclosed engine, automatic transmission, 10- to 12-inch wheels, and engine displacement ranging from 50 cc to 250 cc. Scooters have a floorboard, no pedals for propulsion, and may have a passenger seat.[14,18,19]

In California, the operator of a scooter must pass the same licensing tests as motorcycle operators; scooters must be registered annually. A moped may be operated with any class of driver's license. Annual registration is required for scooters and mopeds without pedals, including mopeds manufactured since 1981.[20]

This research was limited to moped and scooter crashes on public roads in California during 1985 that resulted in either a fatal or severe injury to the driver of the vehicle. General methods of crash injury data collection are contained in an earlier report.[21] Severe injuries are those resulting in a distorted body member or a laceration from which blood flows freely. Off-road injury crashes were excluded.

Fatal and severe injury crashes were identified from the computerized Statewide Integrated Traffic Records System maintained by the California Highway Patrol.

Crash Data and Exclusions

Of the 322 crashes of two- and three-wheel motor vehicles that were not street-legal motorcycles, the following were excluded: 81 off-road motorcycles, 33 all-terrain vehicles, 18 other vehicles that could not be identified.

Information on the vehicle identification number, vehicle license plate number, make, model, and model year was abstracted from the original crash report.

The 1985 California Department of Motor Vehicles registration file provided information on 156,114 two- or three-wheeled vehicles after all motorcycles were excluded. Off-road or all-terrain vehicles (16,649) and scooters or mopeds with registrations expiring before 1985 or first sold in 1986 (41,572) were also excluded. The number of scooters and mopeds at risk of crashing during 1985 was 97,893 in the State of California.

The date on which the vehicle was first sold or registered in California and the registration expiration date were used to

TABLE 1—Fatal and Severe Injury Scooter, Moped, and Motorcycle Crash Rates per 10,000 Registered Vehicle-Years, California, 1985

Vehicle	Crashes	Registered Vehicle Years	Crash Rate	Standard Error*
Scooters	131	34,174	38	3
Mopeds	59	37,286	16	2
Total**	190	75,907	25	2
Motorcycles***	1,832	246,562	74	2

*Calculated as (crashes)$^{1/2}$/(registered vehicle-years).
**The total includes 4,447 registered vehicle-years for scooters and mopeds that could not be classified as to type.
***Motorcycle data from reference 21.

estimate potential use-months during 1985. The scooters and mopeds registered in 1985 represented 75,907 potential use-years.

The 17-character Vehicle Identification Number was used to distinguish scooters and mopeds from other two- and three-wheel motor-powered vehicles.

Data on motorcycle crashes from a previous report[21] are included for comparison. The chi-square statistic was used to test for homogeneity between results for scooters, mopeds, and motorcycles.

Results

Almost 69 percent of the 190 total crashes involved scooters and 31 percent involved mopeds. Scooters had more than twice the crash rate of mopeds, although both rates were considerably less than the rate for motorcycles (Table 1).

The percentages of fatal injury crashes were 8.5 for mopeds, 11.4 for scooters, and 19.6 for motorcycles. The odds of motorcycle fatal injuries compared to those of mopeds and scooters was 1.9 (95% confidence interval = 1.2, 2.9).

Over 59 percent of injured scooter operators and almost 41 percent of injured moped operators were under 20 years of age (Table 2), compared with less than 20 percent of injured motorcycle operators. Nearly 5 percent of the scooter crashes and about 7 percent of the moped crashes involved an operator less than 15 years of age.

In the fatal and severe scooter and moped crashes, 79 percent of the operators were male. Over 98 percent of injured motorcycle operators were male.

Broadside (either vehicle) collisions accounted for 41 percent of the scooter crashes and 51 percent of the moped crashes (Table 3). With the data available, we could not distinguish which vehicle was struck in broadside collisions.

Scooters and mopeds have considerably higher proportions of broadside and rear-end collisions than do motorcycles. Motorcycles, however, overturned* and hit objects more often than did scooters and mopeds.

Scooters and mopeds crashed most frequently in spring and fall, and the highest proportion of crashes occurred on Monday and Friday. More than 60 percent of all scooter and moped crashes occurred between noon and 8:00 pm, and fewer than 10 percent occurred between 2:00 am and 10:00 am. Motorcycles crashed most frequently in the summer and on Saturdays and Sundays. Fifty-one percent of motorcycle crashes occurred between noon and 8 pm.

*Defined by the California Highway Patrol as falling to the ground without a preceding collision.

TABLE 2—Number and Cumulative Percentage of Fatal and Severe Injury Scooter and Moped Crashes According to Age of Operator, California, 1985

	Scooters			Mopeds			Motorcycles		
Age (years)	Number	Percent	Cumulative Percent	Number	Percent	Cumulative Percent	Number	Percent	Cumulative Percent

Overturn	7	5.3	4	6.8	245	13.4
Other	4	3.0	1	1.7	33	1.8
All Types	131	100.0	59	100.0	1832	100.0

Over 87 percent of fatal and severe scooter and moped crashes occurred in urban areas. About 95 percent of the crashes occurred on streets and roads that are not state highways compared with 79 percent of motorcycle crashes.

Discussion

Scooters have a higher crash rate than mopeds. This could represent different usage patterns or a different crash risk with similar usage.

The higher percentage of severe injury crashes as opposed to fatal crashes, for mopeds and scooters compared with motorcycles, suggests different patterns of use and speed capabilities of these vehicles.

The higher proportion of scooter and moped crashes involving a collision with another motor vehicle may be due to their frequent use in urban areas and their decreased visibility to other motorists due to their smaller size.

Teenagers had the highest number of fatal and severe injury scooter and moped crashes, which is consistent with the observation that these vehicles are used principally by adolescents and young adults.[8,14] Because scooter and moped crashes occur mostly among teenage drivers, countermeasure efforts might be most effective if directed specifically toward this population.

ACKNOWLEDGMENTS

Call for Abstracts for PREVENTION 91

PREVENTION 91, the eighth annual national disease prevention and health promotion meeting sponsored by the American College of Preventive Medicine and the Association of Teachers of Preventive Medicine as well as numerous co-sponsors, will be held in Baltimore, Maryland March 16–19, 1991. The meeting theme, "Building an Economic Framework," will be the focus of four days of general sessions, concurrent sessions, poster sessions, workshops, and computer demonstrations.

Abstracts are sought for presentations at PREVENTION 91 which are directly linked to the meeting theme or to one of the topics already selected as the focus for the concurrent scientific sessions. Abstracts must be submitted on the standard abstract form, which may be obtained from: Hazel Keimowitz, PREVENTION 91, 1015 15th Street, NW, Suite 403, Washington, DC 20005. Tel: (202) 789-0006. Abstracts must be postmarked by October 1, 1990 to qualify for this year's consideration.

PREVENTION 91 will present up to six $100 awards to residents/students who submit and present the best abstracts describing their research. Selection criteria include rigorous scientific methodology, clarity, organization, originality, and relevance to the meeting theme.

City Directories as Sources for Survey Work in Low- and Middle-Income Black Communities

EDWARD J. STANEK III, PHD, HARRIS PASTIDES, PHD, WILLIAM A. DARITY, PHD, AND MARY ELKINS, MS

Abstract: Commercial directories and governmental lists of dwelling units in low income urban Black communities in four eastern cities were evaluated for completeness. With rare exceptions, less than 90 percent of dwelling units were included in any one list and no list adequately identified multiple dwelling unit structures. Since household income is likely to be lower among households in such structures, all lists tend to miss the very poor, i.e., those who may be at highest health risk. (*Am J Public Health* 1990; 80:1125–1126.)

Introduction

Community-based surveys are commonly used for needs assessment and program evaluation. The starting point for postal or personal interview surveys is a list of dwelling units (DUs) (or individuals) in the study community. There are usually several possible sources for such lists. An important factor in selecting a list is the degree to which a list covers the actual target population. The list selected is often the list with the largest number of entries.

Knowledge of coverage is important for interpretation of survey results. Certain commercial lists claim to cover, on average, over 95 percent of the DUs.[1] If coverage does not selectively underrepresent groups of individuals, such lists may be adequate. However, low coverage has been reported for DUs in multiple DU structures[1] and for areas that are hard to enumerate.[2] Socioeconomic status (SES) of such areas is likely to be low, and health risks of residents high. Lack of coverage of DUs in such areas may have an important impact on interpretation of results.

To evaluate the potential for bias due to inadequate coverage of low and middle SES communities, we evaluated coverage in lists from four communities: from Columbia, South Carolina, Durham, North Carolina, Hartford, Connecticut, and Springfield, Massachusetts. We discuss the implications of these results for frame construction and subsequent study interpretation.

Methods

Two commercial and two or three governmental lists (voter and property lists) were available in each community. A field list was also constructed by having study personnel canvass the areas on foot using an established protocol.[3] Coverage of each list was evaluated by comparison with a population frame. The population frame included DUs present in the original field list, along with DUs subsequently verified after combining lists.

Study communities were selected in each city using 1980 census data to include at least 300 DUs with a Black adult, low/middle income level, and non-adjacent to areas used in a larger study. Each community was defined on a census map, and boundaries confirmed by physical check. The communities and lists of DUs are given in the Appendix.

Verified computer lists for each source were edited for duplicates. All commercial and governmental lists were then combined to form a single list representing non-field listing sources with one record per DU. Special computer programs were written in SAS to accomplish the matching.[4] Further details concerning individual lists, and list processing are given elsewhere.[5]

Results

The communities in the four cities differed by number of residential structures, percent of structures that contained multiple DUs, and number of DUs. The number of residential structures contained in the final frames are 445, 273, 213, and 1205, in Columbia, Durham, Hartford, and Springfield, respectively. In Columbia and Springfield, a small portion of the residential structures contained more than one DU (0.9 percent and 5.4 percent), while a larger portion of residential structures were multiple DU structures in Durham (39.6 percent) and Hartford (69.5 percent). The total number of DUs identified per community ranged from 1,334 in Springfield to 396 in Durham. The percent of DUs identified as single DU structures ranged from 10.7 percent in Hartford to 84.2 percent in Columbia.

Results of the comparison of each list with the final frame in each community are summarized in Table 1. The original field list identified between 92.0–95.6 percent of the residential structures in all areas except Springfield. In each city (except Springfield) close to 90+ percent of residential structures were identified by at least one other list. However, 10 lists identified less than 80 percent of residential structures.

Coverage of DUs was lower. Two coverage rates for each list are shown in Table 1, where DUs have been grouped by single or multiple DU structure. In order for a DU to be correctly identified, the street number and apartment number/letter in a source must agree with that given in the final population frame. Field listings resulted in more than 80 percent coverage of DUs from single or multiple unit structures. Other lists covered at most 93 percent of single DUs, and 61 percent of multiple DUs.

Overall, DU coverage via the original field list was 95.2 percent (Columbia), 89.9 percent (Durham), 91.7 percent, (Hartford) and 84.7 percent (Springfield). In contrast, the only lists that identified more than 70 percent of the DUs

correctly were the Polk in Columbia (87.6 percent) and Durham (71.5 percent), and the Tax List in Columbia (74.2 percent). No single list enabled easy identification of multiple DU structures, so as to be useful for targeted list up-dating. The same set of DUs were missed by all lists.[5]

Discussion

The results of this study illustrate the limitations in coverage of existing lists of residential structures and dwelling units in low income urban communities. Low coverage has implications for estimation of community health parameters and interpretation and generalization of study results. As confirmed here, dwelling units not included in a sampling frame are not likely to be missing at random. Missed DUs are likely to be from multiple unit structures or those having no visible identifying number. Such households are likely to differ by income/education from DUs that are listed. If response parameters, including a wide variety of risk factors or exposures, differ by such characteristics, estimates of population parameters not adjusting for differential coverage will be biased. Greater efforts are needed to identify possible variables that differentiate DUs (and household members) included or excluded from sample frames.[6] A healthy skepticism is warranted for characterizations of populations that do not account for such possible biases.

Predictors of Vaccination Behavior among Persons Ages 65 Years and Older

PAUL A. STEHR-GREEN, DRPH, MPH, MARY ANN SPRAUER, MD, MPH, WALTER W. WILLIAMS, MD, MPH, AND KEVIN M. SULLIVAN, MPH, MHA

Abstract: We estimated influenza vaccination coverage of 32 percent among persons 65 years of age and older from the 1987 Behavioral Risk Factor Surveillance System survey. Race other than White, obesity, lack of seatbelt use, and current smoking were associated with decreased likelihood of having been vaccinated. Controlling for these factors, the best predictor of having received influenza vaccination was having had a medical checkup within the last year (Odds Ratio = 2.40, 95% confidence interval = 1.84, 3.14). (*Am J Public Health* 1990; 80:1127–1129.)

Introduction

Influenza annually accounts for substantial morbidity and mortality in the United States, especially in older persons. Influenza resulted in an average of approximately 20,000 excess deaths per year during six influenza epidemics from 1972 to 1981, primarily among persons ages 65 years and over.[1] Influenza vaccine has been shown to be approximately 75 percent effective in reducing deaths from influenza and its complications among high-risk older persons living in institutions.[2] Annual vaccination against influenza is recommended for all persons ≥ 65 years old.[3–5] Yet, despite the continuing morbidity and mortality caused by influenza among older adults, most do not receive annual immunization. The purpose of this study was to identify sociodemographic and health-related attributes that may be associated with influenza vaccine coverage among persons ages 65 years and older.

Methods

Data were analyzed from the 1987 Behavioral Risk Factor Surveillance System (BRFSS), a state-based system which monitors self-reported risk behaviors through monthly telephone surveys of adults.[6] Thirty-one states and the District of Columbia participated in the 1987 BRFSS. A sample of households was selected using a multi-stage cluster sampling design. Individual households within eligible clusters were selected for contact by random-digit dialing.[7] After contacting a household, a respondent was selected randomly from all adults residing in the household.[8] In addition to questions on demographic and lifestyle/behavioral characteristics, one question was asked regarding whether the respondent had received an influenza vaccination within the previous 12 months.

We assessed risk factors (i.e., demographic factors, health "risk-taking" behaviors, and preventive health practices) for differential influenza vaccination coverage levels using weighted data (to compensate for sources of variation in selection probabilities).[9] We calculated estimates of the relative likelihood of having received influenza vaccination among groups with specified characteristics using methods which take into account the complex sampling design.[10] In order to simultaneously control for all demographic and behavioral variables, we also used mutivariate logistic regression to discern whether each of the various demographic and behavioral factors were significantly associated with the likelihood of having received influenza vaccination.

Results

Interviews were completed for 9,851 respondents who were 65 years of age or older; 9,799 (over 99 percent) reported knowing whether or not they had received an influenza vaccination within the previous 12 months. Of these, 32 percent reported having been vaccinated against influenza.[11]

There were no important differences in vaccination coverage among persons 65 years of age or older based on gender, education level, or household income (Table 1). Within employment subgroups, retired persons had the highest vaccination coverage (33 percent vaccinated), followed by persons currently working outside their homes (30 percent), homemakers (27 percent), and those currently unemployed (19 percent); in general, persons employed outside their home were equally as likely to have received the vaccination as those without outside employment. Of the demographic factors, race was most strongly associated with having received influenza vaccination. Whites reported higher vaccination coverage levels (34 percent vaccinated) than did Blacks (22 percent) and Hispanics (16 percent); overall, Whites were significantly more likely than other races to have had influenza vaccination (Relative Risk (RR) = 1.63, 95% CI = 1.38, 1.93). This observation held within all household income strata.

When health "risk-taking" behaviors were examined, persons who were obese (RR = 0.86, 95% CI = 0.76, 0.97), persons who did not regularly use seatbelts (RR = 0.89, 95% CI = 0.80, 0.99), and current smokers (RR = 0.80, 95% CI = 0.68, 0.93) were less likely to have received the influenza vaccine (Table 1). There were no differences in vaccination coverage among older persons who were users of smokeless tobacco products, at risk for acute or chronic alcohol consumption problems (including self-reported drinking and driving), or who had a sedentary lifestyle.

The general characteristics that were most strongly associated with whether persons over 64 years old received an influenza vaccination during the preceding year were those related to knowledge and utilization of other health care services (Table 1). Persons who had had a medical examination within the preceding year were twice as likely to have received influenza vaccination than persons who had not had a checkup within the preceding year. Persons who had ever

TABLE 1—Relative Risks of Receipt of Influenza Vaccine by Demographic and Behavioral Risk Factors among Persons 65 Years of Age and Older[a]—Behavioral Risk Factor Surveillance System, 1987

Risk Factors	% with Risk Factor	% Vaccinated in Risk Group[b]	Relative Risk[c]	95% CI[d]
Demographic Characteristics				
Male sex	33.6	34.1	1.09	(0.98, 1.22)
White race	89.2	33.8	1.63	(1.38, 1.93)
High school graduate	56.5	32.1	0.98	(0.88, 1.09)
College graduate	12.6	36.3	1.14	(0.98, 1.33)
Low income (< $10,000/yr)	37.5	31.9	0.98	(0.87, 1.10)
Employed outside home	9.1	29.8	0.91	(0.75, 1.11)
Health Risk-taking Behaviors				
Obesity	28.8	29.4	0.86	(0.76, 0.97)
Lack of seatbelt use	36.8	29.6	0.89	(0.80, 0.99)
Current smoking	13.3	26.5	0.80	(0.68, 0.93)
Use of smokeless tobacco	3.6	31.2	0.96	(0.72, 1.28)
Acute drinking problem	2.1	39.3	1.22	(0.83, 1.78)
Chronic drinking problem	2.7	25.4	0.78	(0.56, 1.08)
Drinking and driving	0.2	17.5	0.54	(0.25, 1.15)
Sedentary lifestyle	67.5	31.9	0.96	(0.86, 1.08)
Utilization of Health Care				
Medical exam in last year	80.0	35.9	2.00	(1.73, 2.31)
Ever told had hypertension	45.6	30.0	1.18	(1.06, 1.31)
(Women) Know of mammography	85.6	32.1	1.26	(1.04, 1.53)
Ever had mammogram	44.7	36.7	1.31	(1.14, 1.50)
Mammogram in last year	60.2	40.3	1.27	(1.03, 1.55)

[a]Total sample size was 9,799 persons; however, due to incomplete responses for some questions, the effective sample size for individual analysis varied.
[b]Data for each respondent were weighted by a factor that was inversely related to that respondent's probability of selection in order to compensate for sources of variation in selection probabilities.
[c]Ratio of the proportion of persons with the specified demographic or behavioral characteristic who received an influenza vaccination within the last year to the proportion of persons without the specified characteristic who received the vaccination.
[d]95% confidence intervals taking into account the complex sample design.

been told by a health professional that they had high blood pressure were somewhat more likely to have received influenza vaccination; however, among these persons there was no increased likelihood of vaccination in those currently taking antihypertensive medications nor among those who reportedly were still hypertensive. Among women, knowledge and utilization of mammography for breast cancer screening was associated with a greater likelihood of receiving influenza vaccination.

When influences of all demographic and behavioral factors were examined simultaneously, those that were previously shown not to be associated were again not correlated with receipt of influenza vaccination. Estimates of relative risk for vaccination associated with race, obesity, lack of seatbelt use, current smoking, or having been diagnosed with hypertension were essentially unchanged. Having had a medical checkup within the last year remained most strongly associated with having received influenza vaccination (Odds Ratio = 2.40, 95% CI = 1.84, 3.15).

Discussion

Our ability to generalize from these estimates is somewhat limited due to non-random selection of states, possible bias due to differences in immunization levels among persons not included in the survey, inability to verify self-reports of immunization status, and the likelihood that there are other factors affecting receipt of influenza vaccination that were not included in these data. However, these results are consistent with previous studies[12, 13] that show utilization of health care services as a strong predictor of whether or not an individual receives influenza vaccination.

Because a recommendation by a health care provider appears to be one of the most important factors influencing a person's decision to be vaccinated,[13] greater attention among providers to implementing recommended immunization practices could help improve influenza vaccine coverage. Annual influenza immunization should be incorporated into their practices; all other vaccines appropriate for adults (pneumococcal, hepatitis B, measles, mumps, and rubella vaccines, and diphtheria and tetanus toxoids) should be offered at every opportunity.[3–5] Barriers (whether sociocultural, physical, or financial) to health care for older persons should be minimized to provide optimal access to preventive, as well as curative, services. In addition, health education efforts to promote healthier lifestyles (e.g., stopping smoking, routinely using seatbelts, and following appropriate exercise programs) should be expanded to include adult immunization as part of overall health maintenance for persons over 64 years of age.

HIV Seroprevalence and the Acceptance of Voluntary HIV Testing among Newly Incarcerated Male Prison Inmates in Wisconsin

Neil J. Hoxie, MS, James M. Vergeront, MD, Holly R. Frisby, DVM, MS, John R. Pfister, BS, Rjurik Golubjatnikov, PhD, and Jeffrey P. Davis, MD

Abstract: In 1986–88, voluntary and blinded HIV testing was conducted among Wisconsin male prison entrants. The HIV seroprevalence was 0.30 percent in 1986, 0.53 percent in 1987, and 0.56 percent in 1988. The seroprevalence rates among entrants tested voluntarily did not differ from those tested blindly. Voluntary HIV testing was accepted by 71 percent of male prison entrants in 1988; among entrants reporting intravenous drug use 83 percent consented to voluntary HIV testing. Voluntary HIV testing of entrants appears to be an effective screening strategy in Wisconsin prisons. (*Am J Public Health* 1990; 80:1129–1131.)

Introduction

Because intravenous drug use (IVDU) is associated with both criminal activity and human immunodeficiency virus (HIV) infection, many persons sentenced to correctional facilities are at high risk of HIV infection. While most strategies aimed at minimizing HIV transmission in prisons include provisions for HIV testing, there is a divergence of opinion as to whether testing should be voluntary or mandatory. The World Health Organization has recommended against mandatory testing of prisoners.[1] The American Medical Association, however, has stated that mandatory testing is necessary to protect inmates.[2] Currently, 14 states and the Federal Prison System have mandatory testing policies.[3] In the Wisconsin Correctional System HIV testing is voluntary. We conducted HIV seroprevalence surveys among newly incarcerated male inmates in Wisconsin in 1986, 1987, and 1988 to provide HIV seroprevalence estimates and to evaluate the acceptance of voluntary HIV testing in Wisconsin prisons.

Address reprint requests to Neil J. Hoxie, MS, HIV Seroprevalence Epidemiologist, AIDS/HIV Program, Wisconsin Division of Health, P.O. Box 309, Madison, WI 53701-0309. Dr. Vergeront is Medical Epidemiologist and Supervisor of the AIDS/HIV Program; Dr. Frisby is also with the AIDS/HIV Program; Dr. Davis is State Epidemiologist and Chief of the Section of Acute and Communicable Disease Epidemiology; all with the Wisconsin Division of Health. Mr. Pfister is Supervisor of the Retrovirus Laboratory; and Dr. Golubjatnikov is Chief of the Immunology Section; both with the Wisconsin State Laboratory of Hygiene. This paper, submitted to the Journal July 24, 1989, was revised and accepted for publication February 14, 1990.

Methods

In Wisconsin, male inmates are admitted to a central intake facility where they receive medical examinations and provide blood specimens for hepatitis B serologic testing; residual sera are retained in a serum bank. While at the intake facility, all inmates view a HIV-related educational videotape, are assessed individually by a nurse for HIV-related risk factors, and are given the opportunity to provide written consent to voluntary HIV testing with post-test counseling.

In 1986, a random sample of banked serum specimens obtained from inmates incarcerated between January 1 and September 29 of that year was selected, all identifying information was removed from these specimens (specimen blinding), and they were then tested for antibody to HIV. In 1987 and 1988, blinded seroprevalence surveys were conducted among inmates incarcerated between January 1 and August 31 of each year who declined voluntary tests. Results of blinded testing were combined with results of voluntary testing performed during the same periods.

Beginning in March 1988, newly admitted inmates were asked to complete voluntary self-administered HIV risk assessment questionnaires as part of the routine intake procedure. Data on inmate age, race, and place of sentencing were obtained from prison records. The blinded study design was approved by the Human Subjects Committee of the University of Wisconsin-Madison.

Specimens were tested at the Wisconsin State Laboratory of Hygiene for the presence of antibody to HIV by enzyme linked immunosorbent assay (Abbott). Repeatedly reactive specimens were tested by Western blot assay. Specimens with at least two viral protein bands (from among p24, gp41, or gp120/gp160) demonstrated by Western blot assay were considered HIV seropositive.

Data were analyzed using *Epi Info* software (Centers for Disease Control, Atlanta, Georgia). The Yates Corrected Chi Square Text (χ^2) was used. Confidence intervals (CI) for odds ratios (OR) were calculated by either the exact or Cornfield method. Mantel-Haenszel weighted odds ratios were used in the age-adjusted analysis.[4]

Results

In 1986, a 48 percent random sample of sera obtained from inmates admitted during the survey period was blindly tested for antibodies to HIV (Table 1). In 1987, 40 percent of

TABLE 1—Results of Voluntary and Blinded HIV Seroprevalence Surveys Conducted among Newly Incarcerated Male Prison Inmates in Wisconsin, 1986–1988

*The 1986 survey did not include a voluntary component.
**Adult male inmates newly incarcerated during the study periods.

inmates admitted during the survey period were tested voluntarily; banked specimens with sufficient quantity of sera were available for blinded testing of 92 percent of those declining voluntary HIV testing. In 1988, comparable figures were 71 and 89 percent.

The 1986 HIV seroprevalence does not differ from that observed in 1987 (OR = 1.8, 95% CI = 0.4, 10.2) or in 1988 (OR = 1.8, 95% CI = 0.5, 10.4) (Table 1). The HIV seroprevalence among those tested voluntarily exceeded but did not differ from the HIV seroprevalence among nonvolunteers in 1987 (OR = 2.8, 95% CI = 0.6, 17.3) and 1988 (OR = 1.3, 95% CI = 0.2, 12.6). Combining 1987 and 1988 data, 72 percent of HIV seropositive inmates were detected by voluntary testing.

The rate of voluntary HIV testing has exceeded 60 percent since the third quarter of 1987, reaching 71 percent in 1988. The consent rate for voluntary testing decreased with increasing age ranging from 78 percent of those less than 20 years old to 56 percent among inmates 40 or more years of age (χ^2_{trend}, $p < 0.001$). Rates of voluntary consent were not significantly associated either with race or place of sentencing.

In 1988, 989 (78 percent) of those offered the voluntary risk assessment responded; among respondents 246 (25 percent) reported IVDU. Among respondents reporting IVDU, six (2.4 percent) of 245 tested for antibody to HIV were seropositive compared to none (zero percent) among 741 not reporting IVDU. Among all respondents, 76 percent consented to voluntary HIV testing. Among respondents who reported IVDU, 83 percent (203 of 246) consented to voluntary HIV testing compared to 74 percent (550 of 743) not reporting this behavior (age adjusted OR = 1.8, 95% CI = 1.2, 2.6).

Discussion

Nationally, HIV seroprevalence among prison inmates has ranged from 0–17.4 percent.[5–7] In Wisconsin the rate is relatively low and has remained stable over a three-year period. In our sample, HIV infection was strongly associated with IVDU and the comparably low HIV seroprevalence we observed is a consequence of the relatively low HIV seroprevalence among intravenous drug users sentenced to Wisconsin prisons. Our estimate (2.4 percent) of the HIV seroprevalence among male prison entrants reporting IVDU closely concurs with a 1987 estimate (2.3 percent) of the HIV seroprevalence among intravenous drug users enrolled in drug treatment in Milwaukee.[8]

Voluntary HIV testing in prisons would be ineffective if HIV-infected inmates or those at risk of infection, especially intravenous drug users, systematically self-deferred from voluntary testing. This has occurred in non-prison settings.[9] However, in our study, the rate of voluntary HIV testing among inmates reporting IVDU exceeded that of inmates denying this behavior. Moreover, the results of the 1987 and 1988 surveys indicate that HIV seropositive inmates did not systematically decline voluntary testing. Similar results have been reported among prison inmates in Oregon.[10]

Because of the risk of HIV transmission in prison populations, prevention strategies are needed. We believe that voluntary behavior change, facilitated by effective risk reduction counseling, is the most desirable method of reducing HIV transmission. If voluntary behavior change is a goal, well-accepted voluntary testing may be advantageous to mandatory testing because it enables inmates and counselors to establish a relationship based upon consent, thus promoting the acceptance of risk reduction counseling.

In Wisconsin prisons, voluntary HIV testing and counseling is an effective method of screening inmates for HIV infection. Because the results of this study may not be generalizable to areas of high HIV seroprevalence, each correctional jurisdiction that offers voluntary HIV counseling and testing should evaluate their programs to assure that these services are reaching high-risk inmates.

Sixth International Conference on Hypertension in Blacks to Meet in Brazil

The Sixth International Conference on Hypertension in Blacks will be held in Salvador, Bahia, Brazil, August 1–5, 1991, and will feature new research papers and state-of-the-art lectures from a pool of 33 countries throughout the world. Conference highlights include:

- Current concepts of ethnicity.
- Blood pressure distributions in racially mixed populations.
- The physiology of stress and hypertension.
- Advances in pharmaceutical agents acting on the renin system.
- Advances in molecular genetics of hypertension.
- Socioeconomic status, ethnicity and hypertension.
- Culture, diet and cardiovascular disease.
- Hypertension: The interplay of genetics and environment.
- The ongoing process of miscegenation.
- Primary health care and hypertension.

The conference will also feature lectures on Brazilian history and culture, since Brazil has the largest population of persons of African ancestry outside of Africa. Topics include:

- Religious practices in Bahia.
- The African roots of Brazilian art.
- Jorge Amado and modern Brazilian literature.
- Slave rebellions in Brazil.
- History and politics of Brazil today.
- Women in Brazilian society.
- The future of Brazilian society: Challenges and perspectives.

Abstracts must be postmarked by February 1, 1991, and submitted on the standard abstract form, available from: International Society on Hypertension in Blacks, 69 Butler Street, SE, Atlanta, GA 30303. Tel: (404) 589-3810.

Use of Contraception and Family Planning Services in the United States, 1988

WILLIAM D. MOSHER, PHD, AND WILLIAM F. PRATT, PHD

Use of Contraception

The leading contraceptive method overall in both 1982 and 1988 was the pill, but female sterilization was approaching the pill in popularity by 1988: 31 percent of contracepting women were using the pill and 28 percent were using sterilization in 1988.[1] If male and female sterilization are considered together as one method, however, then sterilization was the leading method, used by 39 percent of contracepting couples. Among currently married and formerly married women, female sterilization alone was the leading method. Among never married women, the pill was the leading method by far (Table 1). These findings are based on the National Survey of Family Growth (NSFG), a national sample of women in the United States 15–44 years of age. Personal interviews were conducted in the homes of 8,450 women in 1988, 7,969 women in 1982, and 9,797 women in 1973.

The oral contraceptive pill is the leading nonsurgical method of contraception, and the most effective (except for sterilization) in preventing pregnancy.[2] But it does not prevent the spread of sexually transmitted diseases. The condom is less effective at preventing pregnancy than the pill because it is often not used correctly or consistently,[2] but it is useful for preventing the spread of sexually transmitted diseases. Complete estimates of condom use should therefore include women who rely on their partners to use condoms to prevent sexually transmitted diseases,even if they do not use them to prevent pregnancy. This is a more complex methodological problem which is under study, but not covered in the new reports.

Address reprint requests to William D. Mosher, PhD, Room 840, National Center for Health Statistics, 6525 Belcrest Road, Hyattsville, MD 20782

Condom Use

Among never married women using contraception, the proportion who relied on their partner's use of a condom increased from 12 to 20 percent between 1982 and 1988 (Table 1). The condom, however, is sometimes used in combination with other methods—often, the pill. Women who use the pill, sterilization, or the IUD (intrauterine device) along with the condom are not classified in the statistics cited above, and in Table 1, as using the condom, but as using the other method, because the other is more effective in *preventing pregnancy*.[2] If we count all women who reported that their partners use condoms for birth control in 1988, even if they are using some other birth control method (such as the pill), we get an estimate of about 5.8 million women ages 15–44 whose partners were currently using the condom[1]—about 10 percent of the 58 million women of reproductive age.

The IUD and Female Sterilization

In 1985 and 1986, the IUD was withdrawn from the US market by two of its major manufacturers.[3] As a result, use of the IUD dropped by two-thirds between 1982 and 1988, from 2.2 million women in 1982 to 0.7 million in 1988.

TABLE 1—Number of Women 15–44 Years of Age, Percent and Number Using Contraception, and Percent Distribution by Method Used, According to Marital Status: US, 1982 and 1988

	Total		Never married		Currently married		Formerly married	
	1982	1988	1982	1988	1982	1988	1982	1988
Number of women (thousands)	54,099	57,900	19,164	21,058	28,231	29,147	6,704	7,695
Percent using contraception	55.7	60.3	35.3	41.9	69.7	74.3	55.5	57.6
Number using contraception (thousands)	30,133	34,914	6,765	8,823	19,677	21,656	3,721	4,432
All contraceptors	100.0	100.0	100.0	100.0	100.0	100.0	100.0	100.0
Female sterilization	23.2	27.5	3.7	6.4	26.9	31.4	39.2	50.7
Male sterilization	10.9	11.7	1.8	1.8	15.5	17.3	3.4	3.6
Pill	28.0	30.7	53.0	59.0	19.3	20.4	28.4	25.3
IUD	7.1	2.0	5.4	1.3	6.9	2.0	11.5	3.6
Diaphragm	8.1	5.7	13.4	4.9	6.5	6.2	6.7	5.3
Condom	12.0	14.6	11.6	19.6	14.1	14.3	1.5	5.9
Other	10.7	7.7	11.1	7.0	10.8	8.4	9.2	5.7

SOURCE: Reference 1.

Groups that had relatively high proportions using the IUD in 1982 tended to increase their use of female sterilization by 1988. For example, the percent of formerly married contraceptive users who were using the IUD fell from 12 percent in 1982 to 4 percent in 1988, and the percent using female sterilization rose from 39 percent to 51 percent. The new report and a forthcoming analysis show a sharp increase in the percent of contraceptive users who chose female sterilization among several groups that had higher than average proportions using the IUD in 1982: Black, formerly married, less educated, low income, and Hispanic women.[1,4]

Why has female sterilization become the leading method among married and formerly married women? Previous studies of NSFG data have shown that by age 30, three-forths of ever married women have had all the births they want; a typical woman getting a tubal operation was about age 30 and had two or three births. This means that she had 10 or 15 years remaining when she might be able, but did not want, to conceive. About five out of six women in their late 20s have used the pill, which probably means that they want contraception that is as effective and as unobtrusive as the pill. Now that the IUD is no longer widely available, there are only two methods as effective as the pill: female sterilization and male sterilization. The medical techniques of female sterilization have become markedly easier and safer in the past 20 years, so that sterilization often does not require an overnight hospital stay. Also, insurance coverage of sterilization may have become more common in recent years.[4,5]

The Pill

The pill was introduced in the United States 30 years ago, in 1960. Since then, it has been used by the vast majority of women of reproductive age—40.3 million women ages 15–44 in 1988 have used the pill at some time in their lives; 10.7 million of them were using it in 1988. Among women under age 25, the pill was by far the leading method in both 1982 and 1988. The sharp decline in pill use that occurred among married women between 1973 and 1982 did not continue between 1982 and 1988.[1]

Use of Family Planning Services

Sterilization, the pill, and the diaphragm account for 76 percent of current contraceptive use. All of these methods require medical visits to obtain them initially; use of the pill requires regular visits to renew the prescription and check for side effects. Previous research has shown that pill users have a particularly high rate of use of family planning services, even after their other characterizations are taken into account.[6] In addition, young women often make family planning visits to obtain pregnancy tests or to learn about birth control methods.[7] For these reasons and others, it is important to determine how many women use family planning services, and where they obtain those services.

About 20 million women (35 percent of the 57.9 million women ages 15–44) made one or more visits for family planning services in the 12 months before the survey.[8] This was about the same number as in the 12 months before the 1982 survey. Of the 20 million women, about 13 million obtained these services from a private physician, private group practice, or health maintenance organization (HMO); about 7 million used a clinic. Of the 7 million clinic users, about half, or 3.74 million, used a Title X clinic. Black women, teenagers, and low-income were much more likely to use clinics than other women. Women were also more likely to use clinics for their first visit than for their most recent visit: 58 percent used a clinic at their first visit, while only 36 percent used a clinic at their most recent visit. The age group most likely to have had a family planning visit in the last year was women 20–24 years of age—the age group in which use of the oral contraceptive pill is most common.[4,8]

These are only some of the first findings from the 1988 National Survey of Family Growth. Other reports are planned on such topics as contraception, infertility, marriage and cohabitation, and wanted and unwanted births. In addition, a public use computer tape of the 1988 data has been released, so that interested researchers can explore these and other topics further.

ACKNOWLEDGMENTS

The National Survey of Family Growth was designed and supported jointly by the National Center for Health Statistics, the National Institute for Child Health and Human Development, and the Office of Population Affairs, all of the US Department of Health and Human Services.

Consistent Pattern of Elevated Symptoms in Air-conditioned Office Buildings: A Reanalysis of Epidemiologic Studies

MARK J. MENDELL, MPH, AND ALLAN H. SMITH, MD, PHD

Abstract: Published studies of the relation between type of building ventilation system and work-related symptom prevalence in office workers have been contradictory. A reanalysis was performed of six studies meeting specific eligibility criteria, combining published data with unpublished information obtained from study authors. Five eligible studies were from the United Kingdom, and one was from Denmark. Standardized categories of building ventilation type were created to allow comparison of effects across studies. Within each study, prevalence odds ratios (PORs) were calculated for symptoms in each ventilation category relative to a baseline category of naturally ventilated buildings. Air-conditioned buildings were consistently associated with increased prevalence of work-related headache (POR = 1.3-3.1), lethargy (POR = 1.4-5.1), and upper respiratory/mucus membrane symptoms (POR = 1.3-4.8). Humidification was not a necessary factor for the higher symptom prevalence associated with air-conditioning. Mechanical ventilation without air-conditioning was not associated with higher symptom prevalence. The consistent associations found between type of building ventilation and reported symptom prevalence have potentially important public health and economic implications. (*Am J Public Health* 1990; 80:1193–1199.)

Introduction

Health problems and non-specific symptom complaints apparently related to buildings or indoor air, sometimes referred to as "sick building syndrome" or "tight building syndrome," have been recognized for over 15 years[1]. Although particular chemical,[2] biological,[3] physical,[4] or psychological[5] factors have been implicated in some episodes, specific causes have generally not been identified.[6] Studies of this problem to date, generally carried out in buildings identified by worker complaints (referred to herein as "complaint" buildings) have demonstrated mostly what these episodes are *not*. They are not caused by known toxins at concentrations exceeding current health standards nor are they generally associated with known diseases. We still have little idea how frequently the excess symptoms reported in such episodes actually occur among office workers, or what if any chronic health problems in this population are related to office buildings.

It is difficult to study a phenomenon characterized only by self-reported non-specific symptoms with no accepted syndrome definition or objective tests available. A major weakness of investigations in buildings with widely recognized worker complaints is that occupant concerns are likely to upwardly bias symptom reporting, thus distorting the only outcome available for study. Until the development of useful objective tests, it will therefore be preferable to study buildings without recognized worker complaints (referred to herein as "non-complaint" buildings).

Reports on building-related health problems in the United States are almost without exception case studies of complaint buildings;[2-4,7-10] only one study compared the building under investigation to even a single noncomplaint building.[11] A number of recent European studies, however, have provided data from non-complaint buildings on relations between work-related symptoms in office workers and type of building ventilation.[12-16] Preliminary review of the European studies shows that mechanical ventilation, relative to natural ventilation, has been associated with increases,[12,16] with decreases,[17] and with no differences[22] in work-related symptoms; air-conditioning, has been associated with increases[17] and with no differences[16] in symptoms. Previous reviews of the literature on illness episodes in office buildings[6,27-30] have summarized available studies but have not discussed these discrepancies.

This paper presents a reanalysis of data from non-complaint building studies. The purpose was to determine if there were consistent relations between prevalence of specific symptoms and certain building ventilation factors: mechanical ventilation, air conditioning, and humidification. Although differences between the original studies did not allow direct comparison of results, additional information obtained from study authors allowed creation of a standardized set of ventilation categories, calculation of prevalence odds ratios, and comparison of findings across studies.

Methods

Selection of Studies for Reanalysis

Studies of work-related symptoms in office workers were selected from the literature, using specific eligibility criteria. For inclusion in this reanalysis it was required that:

- studies compared multiple non-complaint office buildings;
- data allowed comparison of prevalence for specific work-related symptoms between buildings of different ventilation type; and
- data were available allowing classification of buildings as naturally or mechanically ventilated, as air-conditioned or not air-conditioned, and as humidified or not humidified.

Six studies of worker symptoms in multiple office buildings[12-26] were included in this reanalysis. The studies included were all cross-sectional and compared work-related symptom prevalence in buildings with different ventilation types to a baseline symptom prevalence in naturally ventilated buildings. All studies tested for statistical independence of ventilation categories and symptom prevalence (using chi square or analysis of variance tests) but used no epidemio-

From the Department of Biomedical and Environmental Health Sciences, University of California, Berkeley (both authors) and the California Department of Health Services (Mendell). logic effect measures (such as prevalence ratios or odds ratios) to assess this relationship. Five studies were conducted in the United Kingdom, and one in Denmark. (Findings of the six studies are summarized in the Appendix.)

Methods of Analysis

Five standard categories of building ventilation type were established, as described in Table 1. Information for this classification was extracted from published materials; where necessary, additional information was obtained directly from the authors, and subsequent classification of buildings was confirmed with them.* Ultimately, sufficient information was available for unequivocal classification of all buildings from the six studies into this common set of categories. Correct conversion of ventilation categories in the original studies to the ventilation categories in this reanalysis was not always straightforward; in such cases, the appropriate conversions are provided in footnotes to Table 2, along with publications from which the data were obtained.

Symptoms were organized into four groups:

- lower respiratory (tight chest, difficulty breathing, shortness of breath, wheeze, and flu-like symptoms);
- upper respiratory/mucus membrane (nose, throat, and eye symptoms);
- central nervous system (headache and lethargy); and
- skin (dry skin, itching skin, and skin rash).

From sample size and prevalence data reported for either individual buildings or groups of buildings in each study, numbers of subjects with and without each specific work-related symptom were calculated within each category of building ventilation type. Prevalence rates were then calculated. "Work-related symptoms" in all studies referred only to symptoms reported as improving on weekends or days away from work (and in study 1 and parts of study 2, also as having begun or worsened since starting work in the current building). Symptom frequency requirements varied between studies.

Baseline symptom prevalence varied widely between studies. Using the naturally ventilated building category as the reference group within each study, prevalence odds ratios and 95% test-based confidence limits[31] were calculated from prevalence rates for each work-related symptom within each of the other ventilation categories. The prevalence odds ratio was chosen as the most informative epidemiologic effect measure for cross-sectional prevalence data.[32,33]

*Personal communications: M. Finnegan, S. Burge, A. Pickering, A. Robertson, J. Harrison, O. Valbjorn.

Results

Table 2 gives the sample sizes for each study reviewed, in terms of number of workers and number of buildings in each ventilation category.

Table 3 gives prevalence data for specific work-related symptoms, as calculated for each study using the new building ventilation categories.

Table 4 gives prevalence odds ratios (PORs) for each work-related symptom in each ventilation category. Symptom prevalence in category II buildings (with simple mechanical ventilation) was comparable to that in category I buildings or lower, with one exception (headache prevalence in study 4, based on only one building in category II). This was in sharp contrast to the general pattern of higher symptom prevalence in air-conditioned buildings (categories III, IV, and V) found in all six studies.

The prevalence of central nervous system and upper respiratory/mucus membrane symptoms was almost without exception higher in the air-conditioned buildings than in the naturally ventilated buildings. Data on lower respiratory problems were relatively sparse and less consistent. Data on skin-related symptoms suggested higher prevalence in air-conditioned buildings.

Data on differences between air-conditioned buildings with different kinds of humidification were mixed. In studies 1 and 3, where these data were available, symptom prevalence in buildings with steam humidification was similar to that in those with no humidification. There was some suggestion in both studies of higher symptom prevalence in buildings with water-based humidification relative to both categories III and IV. For 18 of the 21 symptoms assessed between these two studies, point estimates in category V equaled or exceeded those in both categories III and IV.

In study 2, on the other hand, symptom prevalence in air-conditioned buildings with water-based humidification was generally comparable to or lower than that in air-conditioned buildings without humidification. More complete data from this study, however, were presented at a scientific meeting. They showed consistently *lower* symptom prevalence in air-conditioned buildings with water-based humidification than in those without humidification; symptom prev-

*Source: Reference 15 was used, as it included an additional, steam-humidified, building not included in the initial report, reference 12, and it omitted two buildings included in the initial report specifically because of worker complaints. Category III buildings were described as having "mechanical ventilation."

**Source: Reference 16. Category III buildings were described as having "mechanical ventilation only." Category V buildings were described as "fully air-conditioned, with or without recirculation," or "humidified."

***Source: Reference 17 was used for data in categories I and II, but reference 19 was used for categories III-V, as it was the only report to include data from air-conditioned buildings by type of humidification, for all symptoms.

†Source: Reference 20. Category I buildings were described as "conventional" and category II as "unconditioned."

††Source: Reference 21.

†††Source: Reference 22. Data used were from the 14 town halls; buildings number 10, 20, 30, 40, 50, and 90 were in category I, number 121 was in category V, and the rest were in category II.

alence was still substantially higher than in naturally ventilated buildings.**

Buildings without natural ventilation may be sealed (i.e., have non-operable windows) or not. Although sufficient information was not available to allow incorporation of this factor into ventilation categories used for reanalysis, enough information was available to show a very strong relation between the presence of air-conditioning and presence of sealed windows in the buildings studied: only one of the 48 non-air-conditioned buildings had sealed windows, whereas 52 of the 57 air-conditioned buildings had sealed windows. Thus, given the limits of these data, symptom increases found to be associated with air-conditioned buildings may more appropriately be regarded as associated with air-conditioned, sealed buildings.

Discussion

This reanalysis suggests that sealed buildings with air-conditioning are associated with higher prevalence of work-related headache, lethargy, and eye, nose, and throat symptoms than unsealed buildings with no air-conditioning, even in the absence of humidification. It also suggests that although air-conditioned buildings with steam humidification are associated with symptom prevalence no higher than air-conditioned buildings without humidification, air-conditioned buildings with water-based humidification *may* be associated with higher prevalence of eye, nose, and throat symptoms than those with steam humidification.

Apparent discrepancies between the original reports were resolved by reclassification based on new information from authors of the studies. Buildings described as mechanically ventilated were actually air-conditioned without humidification in studies 1 and 2, and simply mechanically ventilated in study 3; in study 6, they were simply mechanically ventilated or, in one case, air-conditioned with water-based humidification.

The prevalence of some work-related symptoms was strikingly high in several studies in even the least problematic office buildings, suggesting a measurement problem. High prevalence of lethargy in category I buildings in studies 3 and 5 (50 percent and 62 percent) in fact reflects a very broad definition of "work-related" symptoms in these two studies, the least restrictive such definition in all studies reviewed (see Appendix). (That such high prevalence resulted from specifics of the study protocol is evident from the fact that study 5 remeasured buildings from study 1 with the protocol from study 3, and obtained prevalence estimates two to four times those in study 1, comparable to those in study 3.)[21] Symptom prevalences reported in study 6, also somewhat high, represented combinations of two to three specific symptoms assessed.[10] Such differences emphasize the need for standardized questionnaire design and data reporting.

One must be cautious in generalizing results of this reanalysis. The studies reviewed were all carried out in the United Kingdom or Denmark, and other countries may have differences in climate as well as in building and ventilation system design or operation.

Also, limitations in the data restrict conclusions that can be drawn from this reanalysis, due to a variety of possible biases in each study.

Bias from selection of buildings seems unlikely, as buildings in all studies were selected independently of worker complaints. Response bias among workers also seems unlikely, as response rates were high in all studies (see Appendix). Some selection bias due to cross-sectional study design

*Prevalence data originally reported as integer values.

is possible as workers who left the workplace due to illness or discomfort were not included, but this would lead to underestimation of any real effects.

Because "negative" (non-significant) studies are generally less likely to be submitted or accepted for publication, reviews of the literature are likely to contain a disproportionate number of studies with positive findings, relative to all studies actually performed on that subject.[34,35] Publication bias may in this way have inflated the magnitude of associations in this review; however, larger studies are considered less prone to this bias,[35] and PORs for air-conditioned buildings were consistently elevated even in the largest studies reviewed. Furthermore, a consistent "negative" finding of this reanalysis was not subject to such bias: symptom prevalence in simply mechanically ventilated buildings was no greater than that in naturally ventilated buildings.

Possible information biases include reporting or interviewer bias and misclassification. Reporting or interviewer bias, due to increased worker or interviewer concerns about health in sealed, air-conditioned buildings, could have increased frequency of reported symptoms in such buildings and thus led to overestimation of odds ratios. This bias cannot be ruled out.

Awareness of the research hypothesis by interviewers or subjects could have had a similar effect. Interviewers were used only in study 1, so subjects in other studies could only have inferred hypotheses from the self-administered questionnaires. In study 1, with the highest PORs of all studies reviewed, interviewers conducted most interviews without knowledge of the buildings where subjects worked, and researchers had no prior hypotheses regarding ventilation type and symptoms other than lower respiratory.[12]

Misclassification bias could have occurred from crude classification of the very complex ventilation systems found

in large buildings. The resulting nondifferential misclassification, however, would have led to underestimation of any real effects.

A number of potential confounding factors could have affected results. Some non-building factors known to be related to symptom reporting[17,19,22]—such as particular social and work environments, gender, job types, workplace smoking, and season of measurement—could have introduced confounding if consistently associated with particular ventilation types. There is no evidence that these factors were related to building ventilation type in the buildings studied.

Studies 2, 4, and 5 reported no assessment of potential confounding factors.[16,20,21] Study 1 reported only that smoking prevalence was similar in all buildings studied.[12] For study 3, Hedge, *et al*,[19] performed a multivariate analysis examining simultaneous association of a number of factors with total number of symptoms reported by each individual. They reported that higher overall symptom prevalence was associated with air-conditioned buildings, independently of associations also found between symptom prevalence and various individual, psychological, occupational, and architectural factors.

For study 6, a multivariate analysis found that gender, job category, work activities, and psychosocial job factors were associated with work-related symptoms. Differences in symptom prevalence between buildings, however, remained substantially the same after multivariate adjustment, with symptom prevalence still highest in the single category V building.[23]

Some building-related factors may have caused confounding. Air-conditioned buildings, being on average newer than naturally or simply mechanically ventilated buildings, will be more likely to contain fluorescent lighting,[21,36] inner offices distant from windows, with no natural light,[21] "open-plan" office layouts,[20] newer synthetic materials which emit various organic compounds,[30] and materials with high absorptive surface area (such as carpets and cloth-covered partitions) capable of accumulating and re-releasing physical,

chemical, or biological contaminants.[26,29,30,37] To produce spuriously the associations found, these factors would have to be strongly related to both symptom prevalence and ventilation type.[38] This possibility could not be evaluated in the studies reviewed here.

The patterns of association in this reanalysis suggest that symptom reporting is systematically related to still unidentified factors in sealed, air-conditioned buildings. If bias or confounding factors are not responsible for these patterns, these symptom increases may represent one or more as yet unidentified ventilation-related illness syndromes. Possible ventilation-related risk factors include inadequate fresh air ventilation, reduced thermal comfort, use of chemicals within ventilation systems to kill biologic agents,[27] and recirculation of infectious[39] or allergenic[30] biologic agents. Sufficient environmental data were not available from the studies reviewed to evaluate these factors (see Appendix).

Results of this reanalysis are consistent with increased exposure of workers to biologic aerosols from water within the ventilation system (i.e., on or under air-conditioning cooling coils, which dehumidify ventilation air, and in water-based humidification systems).[17,30] Inconsistent associations found between symptom prevalence and water-based humidification may reflect a dual effect of such systems: reduced risk of respiratory infections from humidification generally,[40] but increased risk of respiratory sensitization to biological contaminants (as in humidifier fever or hypersensitivity pneumonitis) from water-based humidification specifically.[41]

In conclusion, the reanalysis of epidemiologic studies presented here suggests that, at least in some countries, increases in building-related symptoms in offices may not be unusual events, but relatively common events not usually attributed to buildings. Future study of this problem, beyond investigation of complaint buildings, is advisable.

ACKNOWLEDGMENTS

This work was supported by the Health Effects Component of the University of California Toxic Substances Research and Training Program, and by the Environmental Epidemiology and Toxicology Section of the California Department of Health Services. We would like to thank the authors of the studies reviewed herein for their generous cooperation. We would also like to thank Michael Bates, MS, Irva Hertz, PhD, Dennis Shusterman, MD, Charles Becker, MD, and numerous others for their comments on the draft manuscript.

APPENDIX

Summaries of Findings of Six Studies

Findings of the studies included in this reanalysis are summarized here; terms used to describe ventilation categories are from the studies themselves.

The first study,[12–15] involving eight buildings, found higher symptom prevalence associated with mechanical compared with natural ventilation, even higher symptom prevalence for buildings with air-conditioning, and the highest prevalence in buildings with air-conditioning and humidification. Whether air within air-conditioned buildings was recirculated did not markedly affect symptom prevalence.

The second study,[16] involving 27 buildings, reported higher symptom prevalence in both buildings with mechanical ventilation and those with air-conditioning and humidification, compared to buildings with natural ventilation. Increases in the two groups were similar. In this study, researchers included several buildings they suspected of having problems; they point out, though, that at that time the sick building syndrome was not known in the United Kingdom.*

The third and largest study,[17–19] involving 47 buildings, found lower symptom prevalence in buildings with mechanical ventilation relative to those with natural ventilation, higher prevalence in buildings with air-conditioning, and the highest prevalence in two subsets of buildings with air-conditioning: those with evaporative humidification,[18] and those with "water-based" air-conditioning systems (this refers to method of cooling the building[42,43] and is not related to type of humidification).

The fourth study,[20] involving five buildings, found prevalence of all symptoms measured to be higher in air-conditioned buildings relative to conventional (not defined in report), but prevalence of only one symptom higher in unconditioned buildings relative to conventional buildings.

The fifth study,[21] involving two buildings, found higher symptom prevalence in an air-conditioned, humidified building relative to a naturally ventilated one.

The sixth study,[22–26] involving 14 buildings (minimal data were reported on some additional buildings), found symptom prevalence in mechanically ventilated buildings higher, but not significantly so, than in naturally ventilated buildings. The oldest town halls had the lowest prevalence of symptoms.

The first two studies used physician-administered questionnaires, and defined work-related symptoms as those occurring more than twice in the previous year, and improving on days away from work;[12,16] symptoms were also required to have started or worsened since working in the current building, except for nose, throat, and eye symptoms in the second study.** All the other studies used self-administered questionnaires. Studies 3 and 5 defined work-related symptoms as those occurring more than twice in the previous year and also improving on days away from work.[17,21] Study 4 defined work-related symptoms as those reported to occur frequently at work.[20] Study 6 defined work-related symptoms as those occurring at least weekly and improving on days away from work.[22] Although individual symptoms were assessed in this study, data were reported only on groups of symptoms.

All studies achieved high response rates among workers in buildings studied—in study 1 from 75–97 percent;[12] in study 2 from 86 percent upward;[16] in study 3 from 67–100 percent, averaging 92 percent;[17] in study 5 averaging 97 percent;[21] and in study 6 from 61–93 percent, averaging 80 percent.[22]

No study reported outside air ventilation rates in buildings. In study 1, environmental measurements were taken in only two buildings, one with low and one with high symptom prevalence; no significant differences were found in the parameters measured—dry bulb temperature, globe temperature, relative humidity, air moisture content, air velocity, positive and negative ions, carbon monoxide, ozone, and formaldehyde.[14] In study 2, levels of airborne particles, as well as viable fungal and bacterial microorganisms, were measured in all buildings studied; no associations were found with symptom prevalence.[16] Study 6 reported that increased symptom prevalence was related to factors such as increased temperature and greater amounts of high surface area materials, open shelving, total floor dust, and potentially allergenic floor dust.[26]

Studies 1 through 5 assessed all buildings between November and March; study 6 between February and May.[22]

Alfred Sommer Named Dean of Hopkins School of Public Health

Alfred Sommer, MD, MHS, a distinguished Hopkins ophthalmologist, epidemiologist and specialist in international health, has been named dean of the Johns Hopkins University School of Hygiene and Public Health, effective September 1, 1990. Sommer succeeds Donald A. Henderson, MD, MPH, who has served as dean for 13 years. The School of Public Health is the largest in the world, with more than 300 faculty members and 1,000 students from 75 countries and projects in nearly 40 nations.

Sommer is professor of ophthalmology at the School of Medicine and holds joint appointments in the departments of epidemiology and international health in the School of Public Health. He is internationally recognized for his pioneering work with vitamin A, in which he found that small, inexpensive doses can save the lives of millions of children around the world. Sommer's discovery came as a result of his work using vitamin A to prevent blindness in malnourished children in Indonesia and other developing nations.

A native of New York City, Sommer, 47, received his medical degree from Harvard in 1967 and his master of health science degree from the Hopkins School of Public Health in 1973.

Sommer is an adviser to numerous national and international groups, including the World Health Organization, the National Eye Institute, the Asian Foundation for the Prevention of Blindness, the International Agency for the Prevention of Blindness, Helen Keller International and the Royal Commonwealth Society for the Blind. He is president of the International Federation of Eye Banks and has published more than 180 papers, reviews or book chapters.

The Association of Corneal Arcus with Coronary Heart Disease and Cardiovascular Disease Mortality in the Lipid Research Clinics Mortality Follow-up Study

LLOYD E. CHAMBLESS, PHD, FLAVIO D. FUCHS, MD, SHAI LINN, MD, DRPH, STEPHEN B. KRITCHEVSKY, PHD, JOHN C. LAROSA, MD, PESACH SEGAL, MD, AND BASIL M. RIFKIND, MD

Abstract: The relationship between corneal arcus (arcus senilis) and mortality from coronary heart disease (CHD) and cardiovascular disease (CVD) is examined in a prospective study of White men (n = 3,930) and women non-hormone users (n = 2,139), ages 30–69, followed for an average of 8.4 years as part of the Lipid Research Clinics Mortality Follow-up Study. After excluding those with clinically manifest CHD at baseline, corneal arcus was strongly associated with CHD and CVD mortality only in hyperlipidemic men ages 30–49 years, for whom the relative risk for CHD and CVD death was 3.7 and 4.0, respectively, after adjusting for age, total cholesterol, HDL cholesterol, and smoking status using a Cox proportional hazards model. Among 30–49 year old males, corneal arcus appears to be a prognostic factor for CHD, independent of its association with hyperlipidemia in this age-group, of about the same magnitude as other common risk factors, underscoring the usefulness of corneal arcus as a prognostic factor to the practicing clinician. (*Am J Public Health* 1990; 80:1200–1204.)

Introduction

Corneal arcus is an extracellular lipid infiltration of the peripheral cornea. It appears as a yellowish-white ring around the cornea, and is separated from the limbus by a 0.3 to 1 mm lucid zone.[1–4] These deposits consist mainly of cholesterol, cholesterol esters, phospholipids, and triglycerides.[1,5] Corneal arcus has been described in children,[3,6] but it is more prevalent among older people and therefore has been often called arcus senilis.[1–6] It occurs more often among Blacks than Whites[4,6,7] and tends to appear earlier in life in Blacks than in Whites.[1–4,6,7]

Rifkind and Dickerson[8] found an association of corneal arcus with coronary heart disease (CHD), and pointed out that its characteristics are similar to those of atherosclerotic lesions: both accumulate in relatively avascular tissues, both increase with age, and are more frequent among males. Data from the Western Collaborative Group Study indicated an association of corneal arcus with the incidence of coronary heart disease in men below age 50.[9] Moreover, it has been found to be related to risk factors of CHD such as hyperlipidemia and to occur more often among patients with familial dyslipoproteinemias.[1–5,6–18] However, data from several studies showed no independent relationship between corneal arcus and CHD and suggested that both were related to elevated serum cholesterol levels.[7,8,12,15,17]

Segal, *et al*,[18] examined the data from the Lipid Research Clinics (LRC) Prevalence Study, which is a major source of information on the occurrence of hyperlipidemia in North America, and found an independent relationship between corneal arcus and the prevalence of CHD. We here report on the relation between corneal arcus diagnosed in White participants of the LRC Prevalence Study based on the mortality from CHD and CVD during a mean follow-up of 8.4 years.

Methods

The methods of the Lipid Research Clinics Prevalence Study and of the Lipid Research Clinics Mortality Follow-up Study have been described in detail elsewhere.[19,20] In summary, the following points are relevant for the present analysis.

Prevalence Study

The Prevalence Study was conducted in the period 1972–76 in 10 Lipid Research Clinics in the United States and Canada. In the first survey (Visit 1), 60,502 individuals (out of 81,926 eligibles) representing a wide ethnic, geographic, socioeconomic, and age variation had their plasma levels of cholesterol and triglycerides determined. A 15 percent random sample of all Visit 1 participants, plus all those with high plasma cholesterol or triglyceride levels or who were taking lipid-lowering medications, plus varying (by clinic) proportions of those with borderline elevation in cholesterol or triglyceride, were invited for a more extensive examination (Visit 2). See Appendix for the definition of "high" and "borderline elevated." Overall, 85 percent of the 12,595 persons eligible for Visit 2 were actually examined. The data used in this analysis, except for a Visit 1 hyperlipidemia variable, were obtained at Visit 2.

Follow-up Mortality Study

All men and women who were at least 30 years old at Visit 2 had their vital status determined annually from 1977 through 1983. Mean follow-up was 8.4 years, with a range of 5.7 to 9.9 years. In case of death, cause was classified as coronary heart disease (CHD), cardiovascular disease (CVD), or due to other causes, using standard criteria.[20] For deaths suspected of being caused by CVD, the cases were reviewed by a panel of cardiologists. They analyzed the death certificate and information obtained from the next-of-kin and from hospitalization records if the person was hospitalized within 30 days prior to death, or from the personal physician if there had been no hospitalization within 30 days prior to

death. Vital status is known for over 99.6 percent of the participants.

Exclusions

Excluded from all CVD analysis were participants with possible or definite CHD at baseline, according to the presence of one of the following: angina pectoris diagnosed by the Rose Questionnaire[21] or during the treadmill test; use of angina medications, antiarrhythmics, digitalis or propranolol; exclusion from the treadmill test because of congestive heart failure, R-on-T type premature ventricular contraction, ventricular tachycardia, parasystolic focus, atrial flutter or atrial fibrillation; or resting ECG evidence of diagnostic or equivocal myocardial infarction.[22] Female users of estrogens or progestogens were excluded because of the small number who had corneal arcus. Black participants were excluded because of small numbers. Individuals invited to Visit 2 because of borderline hyperlipidemia were also excluded for statistical reasons, as explained below, as were individuals invited solely because of use of lipid-lowering medication. Finally, those with nonfasting (<12 hours) or missing lipid values and pregnant women were excluded from the analysis.

Corneal Arcus Diagnosis

The interviewers were trained to identify corneal arcus in the Visit 2 using a uniform protocol.[23,24] They stood in front of the participants so that their eyes were at the same level during the examination, which was usually done in natural (rather than artificial) light, the source of which was tangential to the eye. The upper and lower poles of the eyes were examined. Interviewers were directed to look for a whitish fatty material at the periphery of the cornea. The corneoscleral junction had to be observable for a diagnosis of corneal arcus to be made. For these analyses only positive answers were regarded as indicative of corneal arcus and an "uncertain" response was considered as negative.

Laboratory Methods

A detailed description of the laboratory processing procedures is provided in the LRC Program Laboratory Methods Manual[25] and reviewed elsewhere.[26]

Statistical Methods

Visit 2 sample data are analyzed to draw inferences about a population like that of Visit 1. In order to account in analysis for the sampling scheme, the data are treated as a stratified random sample, with two strata: hyperlipidemics, all of whom were invited to Visit 2, and normolipidemics (including borderline hyperlipidemics), 15 percent of whom were invited to Visit 2. For simplification, the oversampling of borderline hyperlipidemics and of users of lipid-lowering medication were excluded. It should be emphasized that borderline hyperlipidemics were not in general excluded, but only the oversampling invited to Visit 2. Because of the higher proportion of hyperlipidemics in the sample relative to the population, weighting techniques were used in the estimation of overall population parameters.

CHD and CVD mortality rates (deaths per 1,000 person-years of follow-up) were calculated for corneal arcus cases and non-cases, for each age/sex group, by lipid strata and weighted across lipid strata. Confidence intervals or tests of statistical significance are not given for these descriptive statistics, but rather are reserved for the models' fit. Age groups are 30–49 and 50–69. Similar mortality rates were also calculated with respect to other possible prognostic factors besides corneal arcus. These factors are given below, along with cutpoints which define the categories (greater than or equal to versus less than cutpoint) for which mortality rates were calculated:

- Serum cholesterol level (240 mg/dl).
- Fasting serum triglyceride level (250 mg/dl).
- Low density lipoprotein (LDL) cholesterol level (160 mg/dl).
- High density lipoprotein (HDL) cholesterol level (40 mg/dl).
- Body mass index (BMI) (30 kg/m^2).
- Smoking status (current versus ex- or nonsmoker).
- Family history of coronary heart disease (either at least one parent died of CHD or experienced angina before the age of 60 or at least one sibling died of CHD before the age of 60).
- Graded exercise test (positive ECG showed a significant ST elevation or depression or a significant change in the ST integral value—for details see Gordon, *et al*[27]).
- Ischemia on resting ECG excluding myocardial infarction (either evidence of left ventricular hypertrophy or other significant ischemia; Minnesota codes 3.1-3.3 with 4.1-4.3 or 1-3-1 through 1-3-6, or 2.1, 4.1, 4.2, 5.1, 5.2, 6.1, 8.1, or 8.2).

In considering the effects of possible confounding variables on the relation in males aged 30–49 between corneal arcus and CHD and CVD mortality, survival models were fit by lipid sampling stratum, using Cox proportional hazards models. In addition to arcus status, survival status and baseline age, the following baseline variables were considered: continuous [total cholesterol, LDL cholesterol, HDL cholesterol, alcohol consumption (g/day), body mass index (kg/m^2), systolic blood pressure, triglyceride]; dichotomous [family history of CHD (yes = 1, no = 0), smoking (yes = 1, no = 0)]. These variables were added one at a time to the "basic" model, with survival status the dependent variable and corneal arcus and age independent variables, and discarded if the corneal arcus survival association was not changed by their inclusion.

Results

For men free of coronary heart disease at baseline, stratified by two age groups and by lipid sampling strata, the prevalence of corneal arcus, the total follow-up time, the mortality rates from CHD and the relative risk are presented in Table 1. In addition, results are given for the two sampling strata combined, with the stratum-specific results weighted to yield estimates of mortality rates for the Visit 1 population. A high relative risk of CHD mortality was associated with the diagnosis of corneal arcus among hyperlipidemic men under 50 years of age but not among older men. Table 2 shows the same trend when mortality from CVD is considered instead of CHD.

In female non-hormone users, the low prevalence of corneal arcus and the small number of CHD and CVD events preclude any kind of analysis in the younger age group; in the older group, where its prevalence and the number of events increase, the same lack of predictive value for CHD and CVD mortality is observed as in the older men (data available on request to authors).

The proportional hazards models of time to CHD or CVD death (Table 3) show that corneal arcus is an independent prognostic factor for mortality from CHD or CVD in men ages 30–49 years in the hyperlipidemic sampling stratum; for normolipidemic younger men its presence does not appear

TABLE 3—Estimated CHD and CVD Hazard Ratio, Comparing Subjects with Corneal Arcus to Those Without; Adjusted for Age, Total Cholesterol, HDL-C, and Smoking*, Men Aged 30–49 Years

Lipid Stratum	CHD Hazard Ratio	(95 Percent Confidence Interval)	CVD Hazard Ratio	(95 Percent Confidence Interval)
Hyperlipidemic	3.7	(0.9,14.7)	4.0	(1.2,12.9)
Normolipidemic	2.2	(0.3,20.1)	1.3	(0.2,10.4)

*LDL-cholesterol, alcohol consumption, BMI, systolic blood pressure, and triglyceride were also considered, but had no effect on the C.A./survival association, so were discarded.

to be of the same importance. The covariates included are age and those whose inclusion in the model substantially modified the estimates of relative hazard of CHD or CVD mortality as related to corneal arcus. These covariates are total cholesterol, HDL-cholesterol, and smoking. With or without these additional covariates the relative hazards are similar for normolipidemics, but for hyperlipidemics the relative hazards adjusted for age alone are about 1.6 times those for models presented in Table 3.

The relative risk of the diagnosis of corneal arcus in the 30–49 year old male group is compared in Table 4 to that of other possible risk factors. As can be seen there, corneal arcus appears to be at least as statistically strong a prognostic factor for CHD as obesity, hypo-HDL, ischemia on resting ECG, hypertriglyceridemia and family history of CHD, and not very different in magnitude from the relative risk from smoking habit, hypertension, hyper-LDL, and hypercholesterolemia. Details concerning this relation are given in Segal, *et al.*[18]

Discussion

In men under 50 years of age, corneal arcus has been shown in a prospective study to be a predictor of CHD

mortality, independent of presence of hyperlipidemia, and a stronger predictor for hyperlipidemics. Above the age of 50 its diagnosis does not appear to be positively related to the subsequent manifestation of a fatal CHD event. These findings help to clarify previous discussion about this relation,[7,28] confirming the observations made in retrospective,[8,29] cross-sectional,[18,30] and prospective studies.[9] They are in agreement with the interpretation that corneal arcus and coronary atherosclerosis share common determinants in young men, while local factors are more important for its occurrence in older persons.[8,12]

The findings in women confirm the low prevalence of corneal arcus in the young age group,[30,31] which with the low mortality rates rules out the possibility of drawing conclusions about its relation to CHD and CVD mortality. In the older group, where the prevalence of corneal arcus and the mortality rate increase, there is the same lack of relation observed in older men.

The ability to detect patients at high risk of CHD has been of continuous concern, considering the frequent presentation of the disease as sudden death[32] and its devastating consequences, especially in the families of young men. The magnitude of the corneal arcus risk in this age group compared to other usual screening tests (Table 4) highlights the utility of this simple and inexpensive tool as a prognostic factor and reinforces the importance of its diagnosis during the physical examination. This is noteworthy, considering that it had lower prevalence in the baseline of this population-based cohort than in some studies which used hospitalized or referred patients. The fact that, in this study, corneal arcus was detected only by a single examination, without the use of slit lamp, could have resulted in some misclassification.[17] However, such misclassification would be independent of either lipid status or later CHD mortality, so would only bias our results toward the null, that is, toward finding no association between it and CHD mortality. The association between corneal arcus and hyperlipidemia *alone* would suggest evaluation of the lipid profile of young men with corneal arcus. The findings in this paper indicate that it also may be prudent to suggest that all young patients with corneal arcus should undergo a detailed evaluation of their other CVD risk factors.

Environmental Tobacco Smoke Exposure during Infancy

BARBARA A. CHILMONCZYK, MD, GEORGE J. KNIGHT, PhD, GLENN E. PALOMAKI, BS, ANDREA J. PULKKINEN, MS, JOSEPHINE WILLIAMS, AND JAMES E. HADDOW, MD

Abstract: We collected information about household smoking habits from 518 mothers when they made their first well child visit with a 6 to 8-week old infant. A urine sample was also collected from the infant, the cotinine concentration measured, and the measurement correlated with data provided by the mother. Eight percent of the infant urine cotinine values fell at or above 10 μg/L in the 305 households where no smoking was reported. Corresponding rates were 44 percent in the 96 households where a member other than the mother smoked, 91 percent in the 43 households where only the mother smoked, and 96 percent in the 74 households where both the mother and another household member smoked. In households where the mother smoked, infant urine cotinine levels were lower in the summer, and higher when the infant was breast-fed. A screening question about family smoking habits in conjunction with well child care could effectively define a group of infants exposed to environmental tobacco smoke and thus be at greater risk for respiratory diseases. (*Am J Public Health* 1990; 80:1205–1208.)

Introduction

Infants and young children chronically exposed to environmental tobacco smoke (ETS) have a higher risk of developing acute respiratory illnesses than their unexposed counterparts, and hospitalization is more often necessary to manage these conditions.[1–4] The studies defining this risk relied upon family reporting (usually by the mother) of numbers of cigarettes smoked in the household and other locations where the infant or child might be exposed. The availability of biochemical markers capable of measuring tobacco smoke products quantitatively in blood, saliva, and urine now offers the opportunity to obtain a more accurate estimate of actual tobacco smoke absorption by infants and children, irrespective of location. Cotinine, a metabolic derivative of nicotine, has proven particularly useful, because it is chemically stable, is not found in nature (thereby avoiding false-positive test results), can be measured reliably in non-smokers exposed to ETS, and has a circulating half-life of about one day.[5,6] Greenberg, *et al*,[7,8] have recently reported their observations on urine cotinine levels in infants exposed to ETS, documenting the relation between self-reported exposure and urine cotinine levels. The present report provides further data on this relation, based on analyses from a large, population-based study focused on 6 to 8-week-old infants receiving routine well child care in private physician offices and clinics in a mid-sized city in the United States.

Methods

Patient Population

Thirty-seven physicians in the greater Portland, Maine area were asked to participate in the study, and 30 (81 percent) agreed to take part; both of the well child clinics also participated. Following informed consent 518 infant/mother pairs were enrolled at their first well child visit between January and October 1988. Each participating mother answered questions about her age, years of completed education, occupation for both herself and the father, ages of other children, breast-feeding, smoking, number of cigarettes smoked, and smoking habits of others in the household. The age of infants at enrollment was between 6 and 8 weeks. The mean age of mothers in the study was 27.4 years, and they had completed, on average, 13 years of school. For 50 percent of the mothers, this was their first child. To examine the extent to which the study sample represented the childbearing population of Greater Portland, Cumberland County data were analyzed in a 70 percent subset of the county's pregnancies in 1987, all of whom had maternal serum alpha-fetoprotein screening. For both groups, 99 percent were White and average age was 27 years; 9 percent of the study population were not high school graduates compared to 11 percent of the county population.

Urine Collection and Cotinine Assay

It was explained that the urine sample was to be analyzed to learn more about environmental exposures, but cigarette smoke exposure was not specifically mentioned. Two cotton rolls were placed in the diaper at the beginning of the office visit. They were either removed and placed in the glass screw-top specimen vial (if wet) at the end of the office visit or mailed back by the mother if urination had not occurred. This method of urine collection in no way alters the concentration of urine constituents, such as creatinine, and the rate of evaporation of liquid is negligible.[9] Approximately half of the samples were obtained during the office visit. Nine percent of the samples were unsatisfactory for analysis, either because of stool contamination or inadequate volume, and in 81 percent of those cases a repeat urine sample was successfully obtained. Before assaying, the urine was transferred to a test tube by compressing the cotton rolls inside a disposable syringe.

The urine was assayed for cotinine by a competitive radioimmunoassay, using cotinine antiserum raised in rabbits and an iodine ^{125}-label described previously.[10,11] The standard curve of the procedure ranged from 0.25 to 12.0 μg/L, with an estimated lower limit of sensitivity of 0.2 μg/L. A dose-response relationship down to 0.3 μg/L has previously been demonstrated between serum cotinine and ETS exposure with this assay.[10] The lower limit of 1.0 μg/L was selected for detecting urine cotinine, however, to allow for possible assay variability within the 0.25 to 1.0 μg/L range that might result from differences in urine composition and

pH. Consequently, all values below 1.0 μg/L in the present study are assigned a value of <1.0 μg/L.

Results

Figure 1 contains a scatterplot distribution of urine cotinine levels. Among 305 infants who were not exposed to household tobacco smoke, cotinine levels from 97 (32 percent) fell below 1.0 μg/L, and another 185 (60 percent) fell between 1.0 and 9.9 μg/L. Urine cotinine values of 10 μg/L and above were found in only 23 of the infants (8 percent). Overall, the median urine cotinine level in this group was 1.6 μg/L.

Among 96 infants with ETS exposure from other household members only, the median level was 8.9 μg/L; among 43 infants with ETS exposure from the mother only, the median level was 28 μg/L; among 74 infants with ETS exposure from both the mother and other household members, the median level was 43 μg/L. Cotinine values falling at or above 10 μg/L in those categories were: 44, 91, and 96 percent, respectively. The horizontal line drawn at 10 μg/L in Figure 1 represents a reasonable estimate of significant ETS absorption; 94 percent of the infants whose mother smoked had values above this level, as opposed to only 8 percent of the infants in the unexposed category.

Breast Feeding in Relation to Infant Cotinine Levels

Figure 1 also identifies infants who were breast fed (open circles) and those who were bottle fed (closed circles). Among the 401 mothers in the study who did not smoke, 207 (52 percent) breast fed, as opposed to 16 (14 percent) of the 117 mothers who smoked. In households where the mother smoked, breast feeding was associated with significantly higher infant urine cotinine levels, both in the presence of other smokers in the household (urine cotinine medians = 213 μg/L with breast feeding and 39 μg/L without breast feeding, 2-sided t-test on $\log_{10}$ transformed cotinine level, $p = 0.003$), and in the absence of other smokers in the household (urine cotinine medians = 87 μg/L and 25 μg/L, $p < 0.001$).

After excluding breast feeding, regression analyses were performed to examine the relation between number of cigarettes smoked by the mother (exposure) and $\log_{10}$ of the infant urine cotinine level (absorption) both in households where only the mother smoked and in households where others smoked as well. Absorption was related to exposure in both groups (regression coefficient = 0.0155, SE = 0.0068, in the 35 households where only the mother smoked) (regression coefficient = 0.0185, SE = 0.0046, in the 66 households where both the mother and other household members smoked). In both groups, the infant urine cotinine levels differed by a factor of approximately two over the range of exposure.

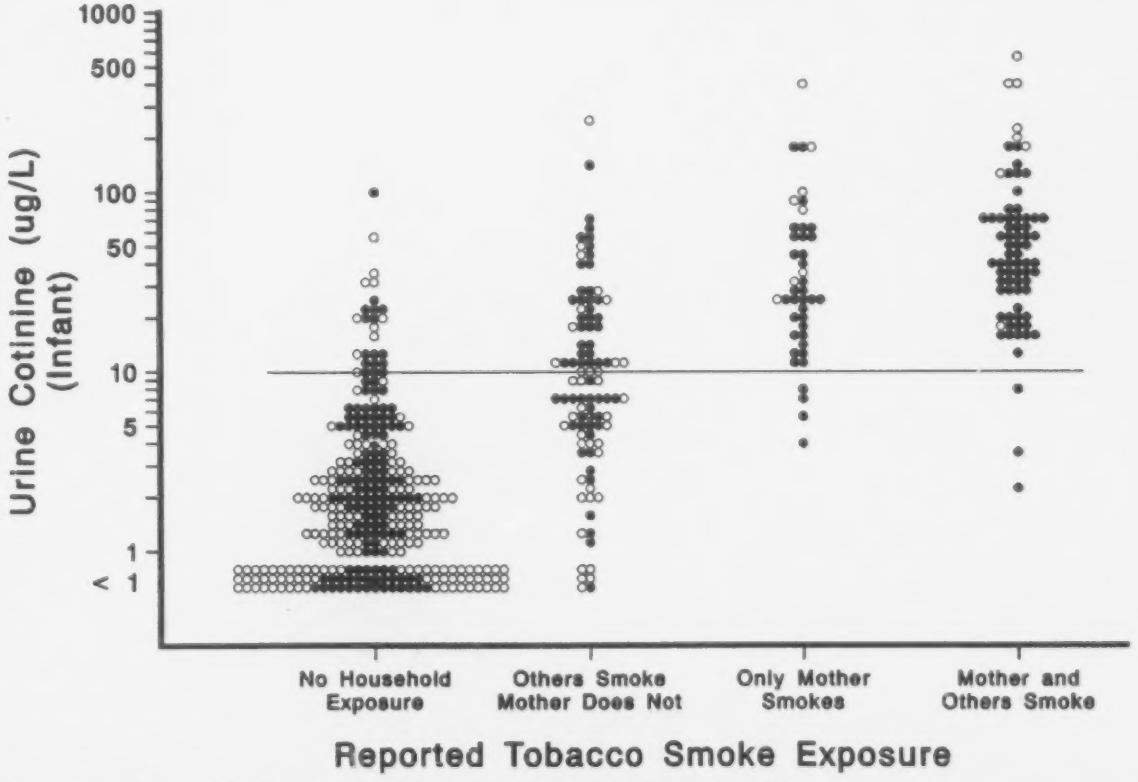

FIGURE 1—Urine Cotinine Levels in Infants, According to Environmental Tobacco Smoke Exposure in the Home.
Cotinine measurements are in spot urine samples. Closed circles indicate that the infant is not breast fed; open circles indicate breast feeding. Cotinine measurements < 1.0 μg/L are considered undetectable, and the horizontal line drawn at 10 μg/L is the cutoff defined from data in the study to indicate significant ETS absorption. Median urine levels in the four groups are as follows: no household exposure—1.6 μg/L; others smoke, mother does not—8.9 μg/L; only mother smokes—28 μg/L; mother and others smoke—43 μg/L.

Influence of Season of the Year on Urine Cotinine Levels in Smoking Households

Table 1 shows, in households where the mother smoked, that the median, 25th, and 75th centiles for infants' urine cotinine levels were significantly lower in the summer (2 sided t-test on $\log_{10}$ transformed cotinine levels, $p = 0.03$); this could not be explained either by the presence of other smokers in the household or by the number of cigarettes smoked by the mother. Preliminary analysis demonstrated no differences between winter, spring, and fall, and so these were combined in the table.

Discussion

Table 2 compares selected characteristics of the present population with those of the population studied by Greenberg, *et al*.[8] The infants in the present study were, on average, 31 days older at enrollment and were primarily Caucasian. The ages, numbers of cigarettes smoked by the mothers, and rate of breast-feeding in mothers who smoked were similar in the two studies. A greater proportion of women in the present study group had finished high school. Greenberg, *et al*, found that infant urine cotinine concentrations were at or above 2 μg/L in 60 percent of their subjects, as compared with 64 percent in the present study, and median cotinine values were also similar (9 and 11 μg/L, respectively) in infants who were not breast fed.

Breast feeding has already been reported to influence infant urine cotinine levels among mothers who smoke,[12,13] and the present study provides further documentation of that effect. Breast milk from mothers who smoke contains high levels of cotinine, and it is likely that ingestion and absorption of cotinine (and also nicotine) explains why breast fed infants of smoking mothers have higher urine cotinine levels than when the mother does not breast feed. Cotinine from this source carries different implications from cotinine produced from inhaled tobacco smoke and needs to be taken into account when using cotinine results to estimate ETS absorption. In the present study household ETS was not reflected in raised infant urine cotinine levels via ingestion in breast fed infants, when the mother did not smoke.

Data from the present study provide evidence, for the first time, of a seasonal influence on infant urine cotinine levels. The lower median cotinine level in infant urine samples during the summer from households where the mother smoked suggests that increased outdoor activity, better ventilation, or a combination, might play a role. When interpreting urine cotinine values, this phenomenon needs to be taken into account, since the average yearly exposure to ETS may be underestimated during the summer months. This variable may behave differently in different climates.

Studies in adults indicate that urine cotinine levels are approximately 10 times higher than those in serum, both in smokers and non-smokers.[10] Since the urine cotinine value reflects exposure over several days, urine cotinine measurements appear suitable both for assessing degree of ETS-related risk and for measuring success following intervention to reduce ETS exposure. The cotton-roll method of urine collection employed in this study is particularly suited for use in the practitioner's office as part of either clinical investigation or ongoing health care counseling.

Our results suggest that a screening question about household smoking habits effectively defines a group of infants with urine cotinine levels of 10 μg/L or above. In our study, 86 percent of all infants with urine cotinine levels at or above 10 μg/L were found in the 41 percent of households where the mother indicated that either she or other household members smoked. Families in which any household member smokes might be considered suitable candidates for further documentation of the extent of infant absorption of ETS. Before implementing this type of approach, however, techniques for teaching families how to avoid infant ETS exposure need to be developed and evaluated.

TABLE 2—A Comparison of Household Smoking Habits and Infant Urine Cotinine Levels in the Present Study and a Recently Published Study

	Greenberg et al[8]	Present Study
Number of Infants	433	518
Average Infant Age at Enrollment (days)	18	49
White (%)	65	99
Mother not High School Graduate (%)	26	9
Mother Smokes (%)	27	23
Average Age of Mother (years)	25	27
Average Cigarettes Smoked/Day By Mother	14	17
Mother Smokes and Breastfeeds (%)	18	14
Household Member Smokes (%) (includes mother)	55	41
Infant Cotinine Value ≥2 μg/L (%)	60	64
Median Cotinine Level for Values ≥2 μg/L (Range)	9 (2–138)	11 (2–261)
Correlation of Mother's Number of Cigarettes versus Infant's Urine Cotinine (r_s value)	0.54	0.39

Drinking Water Contamination and the Incidence of Leukemia: An Ecologic Study

JERALD FAGLIANO, MPH, MICHAEL BERRY, MPH, FRANK BOVE, ScD, AND THOMAS BURKE, PhD, MPH

Abstract: An ecologic study was performed to examine the relation between the incidence of leukemias and the occurrence of volatile organic chemical (VOC) contamination of drinking water supplies within a study area comprised of subpopulations differentially exposed to drinking water VOCs (trichloroethylene and related solvents). Populations served by community water supplies were classified into exposure categories according to VOC contamination status based on 1984–85 sampling data. Leukemia incidence data (1979–84) were collected from a population-based cancer registry. For females, the standardized incidence ratio was elevated only in towns in the highest of three exposure categories. No association was observed in males in any of the exposure categories. A Poisson regression analysis of the data, using finer exposure strata, indicated an increase in risk among females with increasing level of contamination which appeared to be distributed evenly across all age strata. The rate ratio for females at the highest exposure stratum for total non-THM VOCs compared to the least exposed stratum was 1.68. The observed association appears to suggest that drinking water contaminated with VOCs may increase the incidence of leukemia among exposed females, but caution is advised in the interpretation of these results because of the uncertainties inherent in ecologic studies. (*Am J Public Health* 1990; 80:1209–1212.)

Introduction

Since the middle 1970s, there has been considerable epidemiologic interest in the relation between organic contaminants in drinking water and increased cancer incidence in exposed populations. The focus of several studies has been on chlorinated compounds that can form in relatively high concentrations following chlorination of surface water for disinfection. These compounds, some carcinogenic or mutagenic, include the volatile trihalomethanes (THMs) and many nonvolatile substances. There is some evidence that consumption of chlorinated surface water is related to an increased risk of bladder and possibly colorectal cancers.[1–4]

Groundwater was long thought to be relatively protected from such contamination. However, national and state surveys have demonstrated that numerous groundwater supplies throughout the nation have contained volatile organic compounds (VOCs) other than THMs,[5,6] in particular the halogenated solvents trichloroethylene (TCE), tetrachloroethylene (perchloroethylene or PCE), and 1,1,1-trichloroethane (TCA).

In Woburn, Massachusetts, an association was reported between the pattern of VOC water contamination (TCE and others) and the incidence of childhood leukemia.[7] Further epidemiologic analysis of the pattern of non-THM VOC water contamination and the incidence of leukemias is warranted in other geographic areas.

In New Jersey, routine semi-annual testing for 14 VOCs including halogenated solvents has been required of public community water systems since late 1984.[8] Results from 1984 and 1985 showed that about 18 percent of the state's 620 water systems, estimated to serve approximately 20 percent of the state's population, contained detectable levels of non-THM VOCs.[9,10] Data on THM concentrations are also available.

We performed a study of the possible relation between the incidence of leukemia and VOC contamination of drinking water in the state of New Jersey.

Methods

Study Population

In an ecologic study, an ideal geographic area would be completely served by community water systems for which monitoring data are available and would contain subunits that experience a range of contaminant concentrations to ensure exposure differences. The study area that best met these criteria consisted of towns completely within an area bounded by the Lower Passaic River and Saddle River drainage basins. The area is almost completely served by public water supplies, many of which have tapped VOC contaminated groundwater, while others utilize groundwater or surface water free of detectable levels of non-THM VOCs. This portion of the state is primarily urban and residential so that town coding in the Cancer Registry is likely to be accurate, i.e., mailing address and actual residence are likely to be the same.

Towns within the study area were excluded if less than 90 percent of the population was served by public water systems. The age- and sex-specific populations of each municipality were obtained from 1980 US Census summaries.

Exposure Measurement

The New Jersey Department of Environmental Protection compiled all sampling results for each water system serving populations in the study area. The drinking water quality data included the 14 VOCs under the state's monitoring requirements from 1984 and 1985, and THM analyses from 1984 and 1985.

The Department also provided other available sampling data, information on extent of distribution systems, well or reservoir use, and patterns of water purchases among systems so that the water supply of each town could be characterized. Any significant changes in water supply and use patterns in the past decade were noted.

For each water system, we calculated the mean chemical-specific concentrations of VOCs and THMs in distribution system samples for the period 1984–85. Although data were available for later years, the first rounds of monitoring were thought to be more representative of past exposure since corrective actions were taken by many water systems

following the initial results. The number of distribution system samples for each supply varied from two to 50 in the period. Values for each non-THM VOC, total non-THM VOCs, and total THMs were then assigned to each town based on the water supplies that serve that town.

Disease Measurement

Incident cases of leukemias for the towns within the study area were collected from the New Jersey Cancer Registry for the six-year period 1979–84. Information on each case included date of diagnosis, age at diagnosis, town of residence at time of diagnosis, race and sex, and histologic type according to the International Classification of Diseases for Oncology.[11]

Data Analysis

Based on the 1984–85 contaminant values, towns were categorized as to contaminant status for total non-THM VOCs and for THMs. Categorical exposure levels were defined for each variable, empirically derived from inspection of the distribution of values. For each categorical exposure variable, incidence data for the towns within an exposure category were pooled, and standardized incidence ratios for the combined town groups were calculated. Expected incidence for the grouped areas were derived by applying New Jersey statewide 1982 age-sex-specific rates of total leukemias to the pooled 1980 age-sex-specific populations.[12] (Age-sex-specific rates for specific histologic types are not available.) Standardized incidence ratios (SIRs) were calculated by dividing the observed number of cases by the expected number for each town grouping. The 95% confidence intervals of the SIRs were estimated.[13]

Towns sharing the same values for non-THM VOCs were pooled into exposure strata. For each gender, the number of leukemia cases (total and type-specific) in each exposure stratum and age-group specific population was fitted to a log-linear regression model assuming a Poisson distribution of the counts. Separate regression models were developed for total non-THM VOC and for TCE and PCE, two subsets of that variable.[14,15] Predictor variables included in the models were age group (0–19, 20–49, and 50+) and exposure stratum; interactions were also included. Rate ratios were calculated from the parameters generated by the models. Analysis was performed using the GLIM software package.[16] A hierarchical backward elimination method[17] was used to determine final models.

Results

Three of the 30 towns originally contained in the study area were excluded since approximately 50 percent, 4 percent, and 1 percent of their population, respectively, was served by public community water supplies. Approximately 95 percent to 100 percent of the populations in each of the remaining 27 towns in the study area are served by public community water supplies. These 27 towns contained 688,055 persons (324,049 males and 364,006 females), or 9.3 percent of the population of New Jersey in 1980.

Table 1 includes mean total non-THM VOC values assigned to each town or group of towns for the SIR analysis. TCE, PCE, TCA, and dichloroethylenes (DCE) comprised nearly all of the non-THM VOC. Based on inspection of the average values for each town, three categories of total non-THM VOC status were formed: ++ (72–37 ppb), + (12–5 ppb), or − (3 to less than 1 ppb). Two categories of THM status were also formed: + (76–25 ppb) or − (4–1 ppb).

Figure 1 displays the geographic pattern of this categorization. For THMs, 19 towns were rated plus (+) and eight were rated minus (−).

Over the six-year period 1979–84, 208 leukemia cases occurred among males and 164 among females in the entire study area (Table 1). The most frequently reported histologic type among younger age groups of both sexes was acute lymphocytic leukemia (ALL). Among older age groups, chronic lymphocytic leukemia (CLL), acute granulocytic leukemia (AGL), and chronic granulocytic leukemia (CGL)

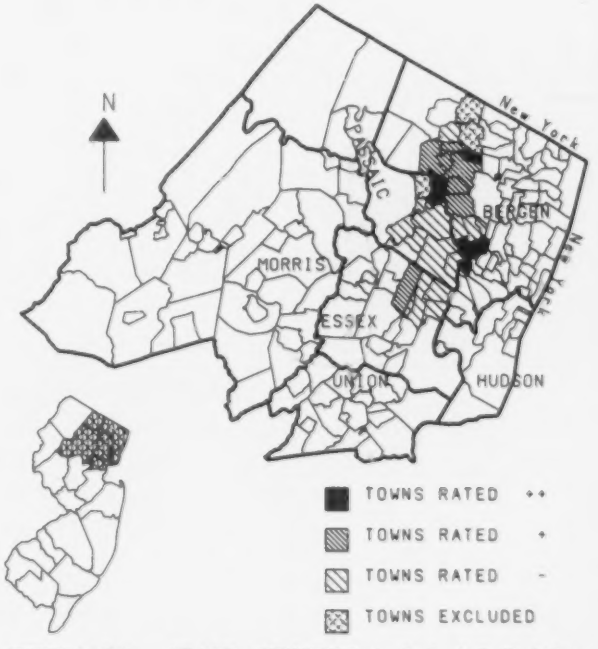

FIGURE 1—Pattern of Total Non-THM VOC Contamination in the Study Area as Categorized for the SIR Analysis

were most frequently reported. Few cases of acute monocytic leukemia were reported, and all were among older males. Twenty-eight percent of the reported cases were coded without specifying histology.

For the entire study area, the observed number of leukemia cases from 1979–84 did not differ from the expected number for either males or females. Among towns classified as ++ for total non-THM VOCs, however, the incidence of leukemia was elevated among females but not in males (Table 2).

No elevation of leukemia incidence was observed for groups of towns classified as either (+) or (−) for THM status among males or females (Table 2).

Regressions were performed for both sexes including categorical age and water quality variables. Results are reported in detail here for females only. The final models of the regression analysis for total leukemias in females (Table 3) do not contain interaction terms between age groups and contaminant status as no p values less than 0.05 were obtained.

The sum concentration of all non-THM VOCs was a statistically significant predictor of total leukemia incidence, adjusted for age. The coefficient for total VOCs was 0.0072 (S.E. =. 0039), and is interpreted as the natural logarithm of the increase in the rate ratio per unit increase in exposure. Thus, for the maximum town average total non-THM VOC concentration observed in the study, 72 μg/l, the rate ratio would be exp[(72 μg/l)(.0072)] = 1.68.

Modeled separately, the age-adjusted coefficients for TCE and PCE concentration were 0.012 (S.E. = .0067) and 0.035 (S.E. = .021), respectively. At the maximum town average TCE and PCE concentrations observed in the study, the rate ratios would be exp[(46 μg/l)(.012)] = 1.74 and exp[(16 μg/l)(.035)] = 1.75, respectively.

When the more common histologic types of leukemia (ALL, CLL, AGL, and CGL) were examined separately, the coefficients for total non-THM VOCs were all of similar direction and magnitude (ALL: 0.016; CLL: 0.0095; AGL: 0.010; CGL: 0.012). There were few cases of each histologic type, hence little power to detect meaningful associations.

TABLE 2—Standardized Incidence Ratios (SIRs) among Males and Females for Groups of Towns Classified According to Various Exposure Categories (Number of cases, 1979–84)

Exposure Category	Number of Cases: Observed	Expected	SIR	(95% Confidence Interval)
Males				
All towns	208	195.7	1.06	(0.92–1.21)
Total non-THM VOCs—1984–85				
++	25	25.0	1.00	(0.65–1.47)
+	38	40.7	0.93	(0.66–1.28)
−	145	130.0	1.12	(0.94–1.31)
Trihalomethanes—1984–85				
+	177	168.5	1.05	(0.90–1.22)
−	31	27.3	1.14	(0.77–1.61)
Females				
All Towns	164	146.8	1.12	(0.95–1.30)
Total non-THM VOCs—1984–85				
++	28	18.3	1.53*	(1.02–2.21)
+	36	30.3	1.19	(0.83–1.65)
−	100	98.2	1.02	(0.83–1.24)
Trihalomethanes—1984–85				
+	140	126.8	1.10	(0.93–1.30)
−	24	20.1	1.20	(0.77–1.78)

*Statistically elevated SIR ($p < 0.05$)

TABLE 3—Poisson Regression Analysis: Final Models for Total Leukemia Cases among Females

Model	Coefficient	Standard Error
	Exposure: Total non-THM VOCS	
Intercept	−1.85	(0.25)
AGE(20–49)	−0.022	(0.32)
AGE(50+)	1.78	(0.27)
TOTAL VOCS	0.0072	(0.0039)
	Exposure: TCE Concentration	
Intercept	−1.83	(0.25)
AGE(20–49)	−0.021	(0.32)
AGE(50+)	1.78	(0.27)
TCE	0.012	(0.0067)
	Exposure: PCE Concentration	
Intercept	−1.85	(0.25)
AGE(20–49)	−0.019	(0.32)
AGE(50+)	1.78	(0.27)
PCE	0.035	(0.021)

Discussion

Results suggest an association between the contamination of drinking water supplies with non-trihalomethane volatile organic chemicals and an increased incidence of leukemias among females. Because of limitations inherent in the study design, a statement of causal inference cannot be made with confidence at this time.

Ecologic studies are practical because they are quick and inexpensive, but because data reflect the group rather than the individual, the results are best used to develop rather than test etiologic hypotheses. Ecologic studies are susceptible to bias in the estimation of effect if there are factors operating at the individual level that are not accounted for in an aggregate exposure assessment. Additionally, at the group level, the degree of correlation among various predictor variables (multicollinearity) is likely to increase, so that the independent effects of predictors may be difficult to isolate. Potential biases and multicollinearity in ecologic studies can be minimized by using narrow exposure strata and regression to estimate effect.[18]

Misclassification of exposure may exist at both the population and at the individual level. In this study, exposure information (1984–85) was collected at the end of the case collection period (1979–84). Although sampling data prior to 1984 are limited, it was our judgment that these data are reasonable proxies for actual levels years earlier. Since the latency period of chemically-induced leukemias can be relatively short—as little as five years or less for benzene[19]—the problems associated with using exposure information gathered after the development of disease may be lessened.

Within a given population classified according to exposure, there may be significant variability of actual exposure to water-borne contaminants experienced by individuals. Individual-level data on personal tap-water use, residential history and migration patterns, and location of workplace or schools compared to residence were not available for this study.

Additionally, confounding variables such as occupational exposures or local toxic air emissions that may be causally related to the development of leukemias, may be correlated with the pattern of water contamination in the study area. However, each town grouping contained towns with both low and high air emission estimates from the recently available USEPA Toxics Release Inventory database.[20]

At least two of the common contaminants, TCE and PCE, have been shown to be carcinogenic in experimental animal studies, indicating the potential to be carcinogenic in humans.[21–25]

Observations in humans exposed to TCE and PCE or related solvents have not demonstrated a consistent association with leukemias. Studies of the mortality experience of dry cleaning workers have variously reported statistically elevated deaths from a variety of cancer sites. Mortality from leukemia was elevated (but not statistically significant) in one of the studies.[26] In a case-referent study of childhood leukemia, fathers' exposure to chlorinated solvents was associated with excess leukemia in the children.[27]

For TCE and PCE, it has been estimated that daily exposures from these chemicals in the ambient air of New Jersey amount to an average of 90 micrograms per day.[28] Using standard assumptions of drinking water consumption,[29] and assuming an equivalent dose from inhaling volatilized contaminants, drinking water concentrations greater than about 20–25 μg/l would add 80–100 μg of exposure, a doubling of the average daily exposure. This estimate illustrates that drinking water can be an important relative source of exposure at levels encountered in some water supplies.

Although we have analyzed total leukemias in this study, we recognize their clinical and etiologic diversity. Known or suspected risk factors include certain genetic traits (particularly for CGL and CLL), ionizing radiation (apparently most types but CLL), infectious agents, and chemicals such as benzene (primarily AML).[30,31] Combining histologic types together in this ecologic analysis may have obscured an effect if the hypothesized etiologic agent, VOC-contaminated drinking water, is specific to a particular histologic type. A detailed analysis of type-specific incidence in this study was precluded by the small number of cases.

The inconsistency of association with respect to gender in this study cannot be explained given the data and level of analysis used in this study.

Our results suggest that a relation may exist between leukemia incidence and VOC contamination of drinking water, at least among females, although this ecologic study cannot lead to a causal inference. Since the observed association may reflect an underlying causal relation, the potential public health importance warrants further study. In particular, a case-referent epidemiologic study would allow an analysis of several potential risk factors and several histologic types that could not be assessed in this ecologic study.

ACKNOWLEDGMENTS

We thank Sandy Krietzman and other staff of the New Jersey Department of Environmental Protection for collecting sampling data and other information on the drinking water systems of the study area, and for reviewing exposure assessment for accuracy. This study was funded under an interagency agreement between NJDEP and the New Jersey Department of Health. Preliminary results of this study were presented at the American Public Health Association 1987 Annual Meeting in New Orleans.

Health Status of Migrant Farmworkers: A Literature Review and Commentary

GEORGE S. RUST, MD, MPH

Abstract: I made a computerized search of MEDLINE files from 1966 through October 1989 followed by a review of this literature. Four hundred eighty-five articles were scanned; 152 were found specifically related to migrant families, while another 51 articles addressed the health of agricultural workers or farmers in general. Solid data exist on dental health, nutrition and, to a lesser extent, childhood health. Data also were prominent in several disease categories including certain infectious diseases, pesticide exposures, occupational dermatoses, and lead levels in children.

Estimates of the size of the migrant and seasonal farmworker population vary widely. Basic health status indicators such as age-related death rates are unknown. Prevalence rates of the most common cause of death in the United States have yet to be studied. More research is needed into the health problems and health status of migrant and seasonal farmworker families. (*Am J Public Health* 1990; 80:1213–1217.)

Introduction

Migrant farmworker families are believed to experience poor health compared to the general population.[1] However, their health status has not been well measured, and many studies have not been published in peer reviewed journals. As a result, large gaps exist in the data on basic health status indicators in the migrant population. The contributing factors to this poor health status are even less well documented. I undertook a literature review to assess the state of our knowledge on migrant farmworker health.

Methods

MEDLINE files from 1966 through October 1989 were searched, using the subject headings of migrants and transients (US), health, agriculture, and agricultural workers' diseases; all articles relating to US populations containing the title word "migrant" or "farmworker" were also scanned. A total of 485 articles were identified through this search, and 203 were judged after further review to make specific reference to the health of migrants, farmworkers, or farmers in the United States.* The bibliographies of these articles were then scanned to identify any relevant articles missed by the computer search. In addition, I had access to one unpublished literature search undertaken for the Bureau of Health Care Delivery and Assistance (USPHS-DHHS) in 1984,[2] and a second literature search first published by the Farmworker Justice Fund in 1985[3] and revised in 1988.[4] The outcomes of these previous literature searches are dealt with in the discussion section of this paper.

Subject matter was divided into 12 categories, including both adult and pediatric health status, health care utilization patterns, health care delivery systems, and eight specific categories of illness by type of disease or organ system. Articles were also analyzed by year of publication.

Address reprint requests to George S. Rust, MD, MPH, Medical Director, Community Health Centers, Inc., (formerly the West Orange Farmworkers' Health Association), P.O. Box 1249, Apopka, FL 32703. This paper, submitted to the Journal July 28, 1989, was revised and accepted for publication May 16, 1990.

Results

Table 1 provides data on the outcome of the search. A further breakdown of the types of articles found by topic and by year of publication (Table 2) illustrates the changing focus of research in migrant health over the past 24 years. The early years were a time of interest in nutritional status, health care delivery systems, and obstacles to health care for the migrant farmworker population. Interest in the risk of pesticides and in the prevalence of infectious diseases showed evidence of continually increasing activity. The first article on AIDS (acquired immunodeficiency syndrome) and HIV (human immunodeficiency virus) seroprevalence in this population appeared in 1987.[5] No articles prior to 1980 dealt with specific psychiatric or behavioral illness patterns, but in the 1980s quantitative studies have begun to appear in the areas of family violence,[6] substance abuse,[7] and specific psychiatric symptomatology.[8]

Topics on which a significant volume of data were found include pesticide risk (including carcinogenic potential), infectious diseases (especially parasites, enteric pathogens, and tuberculosis), and health care delivery. The disciplines of clinical nutrition, dentistry and, to a lesser extent, pediatrics have displayed continuing interest in migrant workers' health.

As early as the 1960s, nutritionists were active in assessing the overall nutritional health status of adults,

children, and pregnant women in the migrant farmworker population.[9] While under-nutrition (protein-calorie malnutrition, vitamin deficiency, and iron-deficiency anemia) was the focus of previous surveys,[10] future studies will be needed to assess areas of over-nutrition such as obesity and hyperlipidemia.

The dental profession has published many studies assessing the dental health of migrant children and adults using a community-based screening approach.[11]

The results of several community-based, health screenings of migrant children have been published.[12] While most of the studies published in the 1970s screened only for lead poisoning, the 1980s have seen some broader assessments. However, none have been performed on a large scale, with unbiased sampling methods and attention to differences among various ethnic groups as well as between the three US migrant streams. Table 3 lists a variety of basic questions on migrant health to which we find virtually no answers in the peer-reviewed medical literature. These are discussed in the following section.

TABLE 3—Unanswered Questions in Migrant Health

A. Population Characteristics
   1. Size of the Migrant and Seasonal Farmworker Population
   2. Age Distribution, Ethnicity, and Family Size of Farmworker Families in East, Central, and West Coast Migrant Streams
B. Mortality and Survival Data
   1. Median Survival
   2. Crude Death Rates
   3. Age Distributions (Mortality curve)
   4. Age-Specific Causes of Death
C. Peri-Natal Outcome Data
   1. Birthweight and Prematurity

   2. Immunization Status
   3. Treatment of Acute Illness Events (i.e., Strep pharyngitis)
   4. Utilization of Recommended Cancer Screening
   5. Delays in Diagnosis/Treatment Prior to Hospitalization

Discussion

The Missing Denominator—How Many Migrants Are There?

In migrant health we lack even such basic data as crude death rates, median survival, infant and maternal mortality, and incidence of permanent disability. One of the major difficulties in computing these is the lack of a precise denominator. We do not know how many migrants there are, because of the transient nature of the population, their migrations into and out of the US (both randomly and seasonally), undercounting of workers who meet the legal definition of a migrant but do not fit ethnic or demographic stereotypes, and the desire of many immigrant workers (documented or not) to avoid contact with government agencies.

The Office of Migrant Health estimates that there are three million "migrant and seasonal farmworkers and their dependents" in the United States.[13] Estimates of the number of "hired farmworkers" in 1985 from the National Agricultural Statistics Service varied from about 1 million (using one method of counting) to over 2.5 million (using a different method).[14] Their surveys were only able to come up with 159,000 "migrant farmworkers" in 1985, a number well below most other estimates.[15]

The Bureau of Labor Statistics asserts that "the size of the hired farm working force declined from an average of 3.6 million in the 1950s to 3.2 million in the 1960s and has been fairly steady at 2.7 million in recent years."[16] The same study notes a decline in the migrant farmworker population from 400,000 in the 1960s to 200,000 in the 1970s.

Several reasons exist for these discrepancies. The first is a question of defining terms. The numbers quoted above do not refer to the same population, but rather to various sub-groups. The Office of Migrant Health's definition is the broadest ("migrant and seasonal farmworkers and their dependents") and therefore gives the largest estimate. The Department of Labor and the Department of Agriculture surveys generally count only employed farmworkers over age 14 (each department using different methodologies).

There are no published estimates of the number of days

worked by migrant workers in a typical year, but with the common use of day-laborers the farm labor force may be expected to have a significant number of days without work. Methods such as those used by the Department of Labor that only count "hired farmworkers" at a given point in time may underestimate the true size of the farmworker population. Similarly, the methodology published by the Office of Migrant Health[17] based on crop acreage and the number of person-hours required to harvest a given crop would also be expected to undercount the farmworker population by an amount proportionate to the number of farmworkers unemployed during that harvest season.

In describing a study population it must always be noted whether a given population estimate is referring only to migrant farmworkers, or to migrant and seasonal farmworkers, or to a composite of farmworkers, crew chiefs, and farm managers. The estimate must also be examined for its inclusion or exclusion of family members and dependents, as well as unemployed farmworkers. Characteristics of the overall population will not necessarily be representative of workers in different geographic streams (East, West, and Central), of workers in different seasons (upstream and downstream) or on different crops, or of the various ethnic and other sub-populations of the farmworker population. Current estimates of the migrant population just do not have the needed accuracy or reliability to be used as denominators in the calculation of morbidity and mortality figures.

Mortality Data

In the study period (1966–89) there was no published study which effectively measured median age of survival, crude death rates, or age-specific mortality in the migrant farmworker population. A literature search commissioned by the Department of Health and Human Services in 1984 reviewed over 400 articles in 60 journals and uncovered only "sporadic documentation" of health problems, none of which included specific mortality or survival data.[2] The Farmworker Justice Fund undertook a similar literature review in 1985 and again in 1988 which documented a variety of occupational and lifestyle-associated hazards, but found no hard data on health indicators.[3,4]

Death certificate data in general has limitations,[18] but there are additional problems specific to migrant farmworkers. In no state is migrant status recorded on the death certificate, so deaths of agricultural workers would include seasonal and homebased farmworkers, thus diluting out the specific health effects of migratory lifestyle. Another problem is the "healthy worker effect," the exclusion of former farmworkers who have returned to their country of origin or who have become unemployed or disabled prior to their death. Members of the extended family, including children, who undoubtedly engage in farm labor may or may not be identified as having a primary occupation.

Perinatal Outcomes

A nutritional survey done by Chase, *et al,* in 1971 in Colorado derived from their maternal interviews an estimate of infant mortality among Mexican American farmworkers in Colorado that was nearly three times that of the general population (63 per 1,000).[19] A more recent study (1978) randomly surveyed 145 married women in migrant farmworker households in Wisconsin.[20] Of these, 132 women had given birth to a total of 629 children (excluding stillbirths). The reported infant mortality rate was 29 per 1,000, while early childhood deaths (age 0–5 years) occurred at a rate of 46 per 1,000. Cause of death was not reported. Large-scale maternal interview studies to define infant mortality in the farmworker population have not been undertaken.

Unfortunately, a large sample of perinatal outcome data from migrant health centers has never been analyzed for publication in the peer-reviewed literature. Migrant Health Centers have been estimated to reach approximately 17 percent (500,000) of the estimated 3 million who live in migrant and seasonal farmworker families.[13] Women receiving comprehensive perinatal care in a migrant health center might be expected to have lower infant mortality rates than those who receive no prenatal care prior to hospital delivery or those whose babies are delivered by a traditional birth attendant, but this has never been documented.

Occupational Risks

In 1987 agriculture surpassed mining as the nation's most hazardous occupation with 1,700 work-related deaths (52 per 100,000 workers). The US Bureau of Labor Statistics estimates that there are 12.7 cases of injury and illness per 100 fulltime workers per year.[21] Several reviews of the specific occupational hazards of agricultural labor are available.[3,22] Hazards include chronic and acute pesticide exposures, lack of safe drinking water and toilets, occupational dermatoses, acute injuries (falling from heights and farm machinery injuries), and chronic low-grade back and joint trauma. Most of these risks have been poorly quantified. One study of emergency room visits for farm equipment injuries suggests a methodology for future studies and monitoring of acute agricultural illnesses and injuries.[23]

The difficulty in quantifying pesticide exposures has been documented best in California, which has the nation's strongest mandatory reporting legislation. The state reported a 30 percent reduction in pesticide poisoning from 1985 to 1986, not from an actual reduction in risk but rather from a change in the criteria for documenting exposures.[24] The scant data that have been published on chronic or low-level pesticide exposure, suggest that limb-reduction birth defects,[25] childhood leukemias[26] and brain tumors,[27] adult lymphomas and lymphosarcomas[28] may be linked with occupational exposure to pesticides.

The Council on Scientific Affairs of the American Medical Association recently reviewed findings of the US Environmental Protection Agency and of the International Agency for Research on Cancer with regard to the carcinogenicity of agricultural chemicals. They report two of 53 chemicals to be *definitely* carcinogenic (arsenic and vinyl chloride). In addition they found 13 of 53 to be *probably* carcinogenic, and 16 of 53 *possibly* carcinogenic.[29] Sharp, *et al,* have also published an excellent review of the carcinogenic and neurotoxic effects of chronic low-level exposure to pesticides.[30]

Disability

A 1974 survey found that 44.5 percent of migrant farmworker households had one or more members who described themselves as disabled, but this study did not obtain clinical correlation of the degree or cause of the disability.[31] No survey of workers for the prevalence of disabling musculoskeletal conditions was found in this review.

Infectious Diseases

A recent study of 709 migrant farmworkers on the Delmarva Peninsula showed a high rate (37 percent) of PPD positivity (10 mm or greater) on TB skin testing, but found only one case of active tuberculosis,[32] suggesting that the

prevalence of tuberculosis among migrant farmworkers may have been overestimated in previous studies which relied on skin testing. The complete absence of articles on the most common infections seen in clinical practice, such as otitis media or streptococcal pharyngitis in children, was striking. Similarly the most common infectious causes of hospitalization among migrants in this author's experience—such as cellulitis, diabetic foot infections, pneumonia, and appendicitis—all are absent from the literature on migrant health.

Chronic Diseases and Premature Mortality

A basic problem with the predominance of research on conventional topics of migrant health—such as pesticides, TB, and parasites—is that it may give disproportionate attention to diseases that are more common among migrants, but still may not be the major cause of their mortality, e.g., cardiovascular disease and complications of diabetes.

There have been a plethora of health care utilization studies documenting the most common diagnoses among migrants seeking health care.[2] What all these studies tell us is that while some uncommon diseases are more prevalent among migrants, common diseases such as diabetes and hypertension in adults still lead the list. From the current literature base it is impossible to calculate the incidence, prevalence, or risk factors for cancer, heart disease, or stroke in the migrant farmworker population, even though these are the most common causes of death in the US.[33]

Socioeconomic Status

Clearly the migrant population is poor—the average migrant farmworker earned only $3,295 per year (1985) from farm labor, and income from all sources was only $6,194.[34] Few studies compared the health problems of farmworker families to other low-income minority groups rather than to the general population. An example of this more meaningful comparison is one which compared blood levels of migrant children to those of a population of urban poor children.[35]

Conclusions

Some progress has been made. Professionals in dentistry and clinical nutrition have made good baseline assessments of the health status of their clients and are now ready to move into on-going monitoring and intervention programs to improve dental and nutritional health status. In other areas we have only small foci of data, often in stereotyped migrant-specific disease categories. New areas such as psychiatric and behavioral morbidities are beginning to be explored, and methodologies are becoming more precise and quantitative. Such studies will need to be undertaken across a broad range of farmworker sub-populations to determine the extent to which results can be generalized to all farmworkers. Other basic indicators of health and disease, as well as the size of the total population and its sub-sets, remain totally unknown.

While services provided by migrant health centers may have improved the overall health of migrant farmworker families by improving their access to health care, there are very limited data with which to prove this point. Neither can it be proven whether the health problems of migrant farmworkers are the same as those of other groups suffering from poverty and powerlessness, or whether there are migrant farmworker-specific factors in their occupation and lifestyle which contribute to death or disease. The fields of undiscovered knowledge in migrant health are vast and ready for harvest. More research is needed.

IVACG Releases Statement on Role of Vitamin A in Child Health and Survival

The XIII International Vitamin A Consultative Group (IVACG) Meeting in November 1989 reviewed the evidence available to date on the relationship of vitamin A depletion and deficiency to childhood morbidity and mortality. Results from completed studies as well as preliminary findings of others underway were presented and discussed by experts from several disciplines. The IVACG Steering Committee realized the need for an interim statement summarizing the weight of evidence available because results from several large, randomized masked trials are unlikely to be available for one to two years. The following statement, released in June 1990, represents the steering committee's careful consideration of the available evidence.

- An adequate vitamin A status prevents nutritional blindness and contributes significantly to child health and survival.
- The role of vitamin A in preventing nutritional blindness is well documented. Evidence is accumulating that it also reduces mortality. The mechanism(s) by which it has this effect is unclear.
- The impact of improved vitamin A nutrition will vary with the severity of vitamin A deficiency and the contributions of other ecological factors.
- It is therefore imperative to improve the diet and raise the level of vitamin A nutrition where a current intake is inadequate.

The IVACG Steering Committee hopes that this statement will be useful in the process of formulating policies and programs to control and combat vitamin A deficiency. The International Vitamin A Consultative Group was established in 1975 to guide international activities aimed at reducing vitamin A deficiency in the world. For further information, contact the IVACG Secretariat, The Nutrition Foundation, Inc., 1126 Sixteenth Street, NW, Washington, DC 20036. Tel: (202) 659-9024.

Paternal Military Service in Vietnam and the Risk of Late Adverse Pregnancy Outcomes

ANN ASCHENGRAU, ScD, AND RICHARD R. MONSON, MD, ScD

Abstract: To investigate the relationship between paternal military service in Vietnam and the risk of late adverse pregnancy outcomes, we conducted a case-control study of women who delivered infants from August 1977 until March 1980 at Boston Hospital for Women. Paternal military service history among 857 congenital anomaly cases, 61 stillbirth cases, and 48 neonatal death cases were compared with that of 998 normal controls. Military service veterans were identified by crossmatching identifying information from obstetric records with state and national military records. After controlling for confounding variables, we found that the Vietnam veterans' relative risk of fathering an infant with one or more major malformations was 1.7 (95% CI = 0.8, 3.5) compared to non-Vietnam veterans. The increased risk was present in several organ systems and did not seem to be related to a particular type of defect. No associations or highly unstable associations were found between paternal military service in Vietnam and the occurrence of congenital anomalies overall, minor malformations, normal variants, stillbirths, and neonatal deaths. These findings should be viewed with caution since maternal and delivery characteristics appear to have contributed to the etiology of several of the major malformations among the Vietnam veterans' children. (*Am J Public Health* 1990;80:1218–1224.)

Introduction

Many Vietnam war veterans have expressed concern that their children are at increased risk of adverse health effects, particularly congenital anomalies, because of wartime exposure to the herbicide Agent Orange.[1–3] The results of studies published to date suggest that the overall risk of congenital anomalies is not greater among Vietnam veterans but that the risk of specific defects or the risk among specific subgroups may be increased.[4–7] We undertook the present case-control study to investigate the relation between paternal military service in Vietnam and a wide range of late adverse pregnancy outcomes including congenital anomalies, stillbirths, and neonatal deaths.

Methods

Study Population

The present analysis used subjects identified for a prior investigation on maternal risk factors for late adverse pregnancy outcomes.[8–9] In the previous study, we enrolled 14,130 obstetric patients who delivered infants at least 20 weeks' gestation from August 1977 until March 1980 at Boston (Massachusetts) Hospital for Women Division of Brigham and Women's Hospital. This represented 82.5 percent of all delivery patients during the study period; lack of personnel was the main reason for not being enrolled.

For the current study, we selected three case groups and one control group from the enrolled patients. The congenital anomaly case group consisted of 1,314 women who delivered live- or stillborn infants with one or more congenital anomalies. The stillbirth case group consisted of 121 women who delivered stillborn infants without anomalies, and the neonatal death case group was made up of 76 women who delivered infants without anomalies but who died shortly after birth. The 1,490 controls were randomly selected from the remaining women who delivered infants without anomalies who were alive upon discharge to achieve an approximate 1:1 case-control allocation ratio.

The original study interview obtained information on maternal demographic characteristics, medical and obstetric conditions, and habits. In addition, the medical records were reviewed to gather information on the delivery and infant characteristics. For the current study, we re-reviewed the medical records for identifying paternal information not previously obtained and for more detailed information on the pregnancy outcome. For women with stillbirths and neonatal deaths, we obtained the underlying cause of death. For women delivering infants with congenital anomalies, we recorded up to five anomaly diagnoses using a modification of International Classification of Diseases 9th Edition developed by the Centers for Disease Control (CDC) (unpublished coding manual). Anomaly coding decisions followed CDC guidelines and were reviewed for accuracy by a dysmorphologist. In addition, follow-up information was sought from pediatricians and hospitals to confirm the cardiovascular defects. Review of medical records and coding of anomalies were done before military service history was determined.

The medical records of 2,599 women (86.6 percent) were located for re-review. Both cases and controls whose records were lost were more likely to be Black, less educated, and younger than women whose records were reviewed. In addition, 507 women whose records were reviewed were unmarried. Among 84.0 percent of the unmarried women as well as 18 married women, we found no identifying paternal information in their medical records.

In the current study, we excluded women whose records were not located for review, unmarried women, married women without identifying paternal information and women with various diagnoses, and the second pregnancy of those with more than one pregnancy during the study period (see Appendix A for details). This left 857 congenital anomaly cases, 61 stillbirth cases, 48 neonatal death cases, and 998 controls for the final analysis.

Military Service Information

We identified military veterans by crossmatching identifying paternal information from the medical record with: the Massachusetts veterans' bonus list and Massachusetts military records, and the military records at the National Personnel Records Center (NPRC) Military Records Division in St. Louis, Missouri. The identification process and review of

From the Department of Epidemiology, Harvard School of Public Health. Massachusetts and NPRC records were performed without knowledge of case or control status of subjects.

Potential Massachusetts veterans were identified by manually searching the bonus list of 250,000 for husbands' names. Potential matches were confirmed by reviewing more complete identifying information in individual military discharge papers. The discharge papers also provided information on the branch, rank, place and dates of service.

Under the Freedom of Information Act, we were able to obtain information on branch, last rank, dates of active service and, if applicable, dates, first rank, and occupational specialty for Vietnam service of all military veterans in our study population. We were denied information on the exact geographic locations of Vietnam service.

In addition to names, Social Security numbers, needed to identify veterans in national records, were obtained from the bonus list for identified Massachusetts veterans and from Massachusetts Registry of Motor Vehicle drivers' license records for the remainder. We located Social Security numbers for 1,641 husbands (83.9% of case husbands and 83.2% of control husbands). Those without numbers were more likely to be Black and born in a foreign country and were included only in the Massachusetts bonus list review.

Analysis

We performed three analyses basing military service history on: 1) the Massachusetts veterans' bonus list alone; 2) national records alone; and 3) both record sources combined. Military service history was categorized as: 1) Vietnam veteran; 2) non-Vietnam veteran; and 3) no known military service.

Husbands were classified as Vietnam veterans if they received a $300 bonus and/or their military records noted the receipt of a Vietnam service medal or listed Vietnam as a place of foreign service. For US Navy personnel, Vietnam veterans were identified by linking individual ship assignments to Naval ship location records. Husbands were classified as non-Vietnam veterans if they received a $200 bonus and/or their military records contained no information on Vietnam service. Husbands were classified as having no known military service if they were not found on the Massachusetts bonus list or if they had no identifiable military records nationally. A national military record was identified but could not be reviewed for four individuals. These husbands were considered veterans with unknown place of service and, when appropriate, were excluded from the analysis.

In the analysis that combined military service information from both Massachusetts and national records, husbands identified as Vietnam veterans in either or both sources were classified as Vietnam veterans. Husbands identified as non-Vietnam veterans in both sources or as a non-Vietnam veteran in one source and as a non-veteran in the other source were classified as non-Vietnam veterans. Husbands were classified as having no known military service if they were classified as such according to both record sources.

To identify Vietnam veterans who might be at increased risk of adverse pregnancy outcomes because of possible exposure to phenoxy herbicides during combat, Vietnam veterans were classified as having probable combat experience on the basis of their branch and occupational specialty by the Director of the Massachusetts Agent Orange Program without knowledge of case or control status of subjects.

We calculated the exposure odds ratio (relative risk) to measure the strength of association between paternal Vietnam service and each type of adverse pregnancy outcome. The odds of each adverse outcome among Vietnam veterans and non-Vietnam veterans was compared to that among men with no known military service. In addition, the odds of each pregnancy outcome among Vietnam veterans were compared to that among non-Vietnam veterans to control for confounding by factors related to entry into military service. Ninety-five percent confidence intervals (CI) for the crude odds ratios were computed using Miettinen's test-based method[10] if there were more than five exposed cases and Fisher's exact method[11] if there were five or fewer exposed cases.

We examined paternal military service history in each case group and then divided the congenital anomaly cases into several subgroups. We categorized anomaly cases according to severity: 1) one or more major malformations; 2) only minor malformations; or 3) only normal variants using a scheme developed by the Metropolitan Atlanta Congenital Defects Program (unpublished procedure manual). Anomalies were also categorized into 13 organ system groups and into specific diagnostic categories. Infants with more than one anomaly diagnosis could contribute to more than one organ system or diagnostic group.

We assessed confounding by entering 44 potential confounding variables into a logistic regression model one at a time and by comparing the adjusted and crude odds ratios[12] (see Appendix B for details). In the regression analyses, the dependent variables included all congenital anomalies, major malformations, minor malformations, and normal variants. Because the number of exposed subjects was small, no adjusted analyses were performed on the stillbirth, neonatal death, and most organ system case groups.

Final logistic regression models were developed for the anomaly cases and severity subgroups that adjusted for several variables simultaneously. The final models included variables that had altered the crude odds ratios by at least 10 percent as well as the following variables of a priori interest: maternal race, educational level, average alcohol consumption during the first trimester, prior infant with a congenital anomaly, and year of pregnancy.

Results

Table 1 displays military service history based on the combined Massachusetts and national data among husbands of cases and controls, and the crude odds ratios of each adverse pregnancy outcome. Compared to men with no known military service, Vietnam veterans, and, to a lesser extent, non-Vietnam veterans had an increased risk of fathering infants with one or more major malformations (ORs = 1.8 and 1.4, respectively). The relative risk of major malformations among Vietnam veterans fell to 1.3 when they were compared to non-Vietnam veterans (95% CI = 0.7, 2.4).

No material increases in the crude relative risks of minor malformations, normal variants, or neonatal deaths were observed among the military service groups. Vietnam veterans had an increased risk of stillbirths but confidence intervals are very wide. The underlying causes of death among stillbirths did not differ among the military service groups.

Most results were similar when military service history was based either on the Massachusetts bonus list or NPRC records alone. However, the relative risks of major malformations and stillbirths fluctuated according to information source. These variations may be accounted for by the small number of exposed cases (data available from author).

Compared to non-veterans, the crude relative risks of defects from several organ systems were elevated both among Vietnam veterans and non-Vietnam veterans (Table 2). The largest increases in risk among Vietnam veterans

TABLE 1—Military Service History, Crude Odds Ratios and 95% Confidence Intervals for All Congenital Anomalies, Congenital Anomaly Severity Subgroups, Stillbirths, and Neonatal Deaths

	Military Service History*			Odds Ratios** Comparing		
	Number of Vietnam Veterans	Number of Non-Vietnam Veterans	Number of Men with No Known Military Service	Vietnam Veterans to Men with No Known Service	Non-Vietnam Veterans to Men with No Known Service	Vietnam Veterans to Non-Vietnam Veterans
All Congenital Anomalies (N = 857)	55	146	656	1.3 (0.9, 1.9)	1.0 (0.8, 1.3)	1.2 (0.8, 1.9)
One or More Major Malformations (N = 214)	18	45	151	1.8 (1.0, 3.1)	1.4 (1.0, 2.0)	1.3 (0.7, 2.4)
Only Minor Malformations (N = 232)	11	32	189	0.9 (0.5, 1.7)	0.8 (0.5, 1.2)	1.1 (0.5, 2.4)
Only Normal Variants (N = 411)	26	69	316	1.2 (0.8–2.0)	1.0 (0.7–1.4)	1.2 (0.7–2.1)
Stillbirths (N = 61)	5	5	51	1.5 (0.4–3.9)	0.5 (0.1–1.2)	3.2 (0.7–14.5)
Neonatal Deaths (N = 48)	3	9	36	1.2 (0.2–4.2)	1.2 (0.6–2.5)	1.1 (0.2–4.5)

*Military service history was based on the combined Massachusetts and NPRC data.
**Odds ratios were computed by comparing paternal military service history of each case group to that of the 995 controls; 52 control husbands were Vietnam veterans, 167 were non-Vietnam veterans, and 776 had no known military service. Three control husbands who were identified as veterans but whose place of service was unknown were excluded.

TABLE 2—Military Service History and Crude Odds Ratios According to Major Malformation Organ System

	Military Service History*			Odds Ratio# Comparing		
Organ System	Number of Vietnam Veterans	Number of Non-Vietnam Veterans	Number of Men with No Known Military Service	Vietnam Veterans to Men with No Known Service	Non-Vietnam Veterans to Men with No Known Service	Vietnam Veterans to Non-Vietnam Veterans

*Military service history was based on the combined Massachusetts and NPRC data.
#All confidence intervals for the odds ratios include 1.0.
†Cardiovascular defects among infants with Trisomy 21 are excluded.

were for malformations of the nervous system, cardiovascular system, genital organs, and urinary tract.

The organ system results were similar but somewhat attenuated when Vietnam veterans were compared to non-Vietnam veterans. The organ system risk estimates should be interpreted cautiously since they were based on a small number of exposed subjects.

When we examined the specific anomaly diagnoses and clinical notes among the 18 major malformation cases whose husbands served in Vietnam (Appendix C), we found that no one diagnosis predominated within an organ system. In fact, only two defects were observed more than once: two infants had a ventricular septal defect, and three infants had talipes (clubfoot).

Maternal and delivery characteristics appeared to be important contributory factors in the etiology of some malformations. Pediatricians consider that the congenital dislocation of hip and clubfoot were secondary to fetal position; both the mother and prior sibling of the case of adrenal hypoplasia had a history of adrenal insufficiency. None of the medical records of these major malformation cases noted that the husband was a Vietnam veteran.

We also examined military service history among five diagnostic categories of skin and related anomalies: abnormal palmar creases (N = 24), sacral dimples (N = 78), hemangiomas (N = 83), benign neoplasms of the skin (N = 25), and other specified skin anomalies (N = 152). The crude relative risks of abnormal palmar creases and sacral dimples were

increased among Vietnam veterans when compared either to non-veterans or non-Vietnam veterans (OR 3.7, 95% CI = 0.8, 12.1 and OR 2.5, 95% CI = 1.2, 5.3, respectively, for the comparison between Vietnam veterans and non-veterans; OR 3.2, 95% CI = 0.6, 17.8 and OR 1.8, 95% CI = 0.8, 4.3, respectively, for the comparison between Vietnam veterans and non-Vietnam veterans). The remaining categories of skin anomalies were not materially elevated among Vietnam veterans nor were any skin anomalies materially increased among non-Vietnam veterans. Because normal variants like abnormal palmar creases can be markers for more serious defects, we reanalyzed these data excluding infants with major malformations. Upon reanalysis, the relative risks of palmar creases and sacral dimples among Vietnam veterans remained elevated.

In Table 3 we have presented the military service characteristics of Vietnam veteran case and control husbands. A greater proportion of congenital anomaly and major malformation case husbands versus control husbands served in the Marine Corps and had longer durations of Vietnam service. Anomaly case husbands were also more likely to have enlisted and have had initial occupational specialties in Vietnam likely to involve combat.

Because Vietnam veterans who were in combat had a greater likelihood for herbicide exposure than veterans who were not,[13] we recalculated the odds ratios for all congenital anomalies and the severity subgroups considering as exposed only Vietnam veterans with probable combat experience. Compared to non-Vietnam veterans, the relative risks of congenital anomalies overall, one or more major malformations, only minor malformations, and only normal variants among Vietnam veterans with likely combat exposure were similar to those risks among all Vietnam veterans (1.4, 1.1, 1.4, and 1.5, respectively). The number of Vietnam veterans with probable combat exposure among the stillbirth and neonatal death case groups was too small to permit meaningful analysis.

Many available characteristics of the study population were potential confounders because of their association with paternal military service history and a particular pregnancy outcome. When we adjusted simultaneously for confounding variables using logistic regression models, we found that the relative risk of one or more major malformations rose to 2.2 for the comparison between Vietnam veterans and non-veterans (crude OR 1.8) and to 1.7 for the comparison between Vietnam veterans and non-Vietnam veterans (crude OR 1.3) (Table 4). The adjusted relative risks for congenital anomalies overall and the other severity subgroups differed little from the crude relative risks. Confidence intervals are again very wide.

Discussion

In our study population, we have observed positive associations between paternal military service in Vietnam and the risk of fathering an infant with one or more major malformations even after controlling for available confounding variables. The increased risk was present in several organ systems and did not seem to be related to a particular type of defect. We also found positive associations between two normal variants of the skin and Vietnam service. No associations or highly unstable associations were observed between Vietnam service and congenital anomalies overall, minor malformations, normal variants, stillbirths, and neonatal deaths.

The positive findings warrant cautious interpretation since maternal and delivery characteristics appeared to be important factors in the etiology of the endocrine and some of the musculoskeletal malformations observed among the children of the Vietnam veterans. In addition, most risk estimates for the organ systems were unstable because they were based on a small number of subjects.

One might also argue that cautious interpretation is needed because of the wide variety of major malformations seen among the Vietnam veterans' children. However, the etiologic implications of the lack of a predominant defect or discernible pattern of defects are unclear, because so little is known about the possible biologic mechanisms by which paternal exposures might influence pregnancy outcomes and because many well-known maternal exposures have been associated with a wide range of defects (e.g. maternal prenatal ingestion of thalidomide has been associated with limb, ear, eye, heart, gastrointestinal tract, and genital organ defects).[14]

‡Unadjusted results.

In the current investigation, congenital anomaly diagnoses were made usually within a few days of birth by pediatric residents who were not specialists in teratology. Thus, it is quite likely that some anomalies were missed. We believe that this misclassification was not related to military service history and so probably biased some results towards the null.

We believe it is unlikely that the positive association observed for major malformations was due to more complete ascertainment of these congenital anomalies among the children of Vietnam veterans. Anecdotal reports of adverse reproductive outcomes among Vietnam veterans potentially exposed to Agent Orange began appearing in the medical literature in late 1979 after most of the study pregnancies had occurred.[1–3] Most of these malformations had very noticeable cosmetic or medical effects and many were life threatening. Thus, it is unlikely that the diagnosis or notation of a defect would be affected by the father's military service history. Furthermore, none of the medical records of the major malformation cases noted that the husband was a Vietnam veteran.

We also regard it as unlikely that these results simply reflect a differential tendency for Vietnam veteran versus non-Vietnam or non-veteran cases and controls to have participated in the original study. For practical reasons, enrollment in the current study was limited to married women whose records contained identifying paternal information. Enrolled women were predominantly White and college educated while the excluded women were more likely to be Black and less educated. Because the demographic characteristics of both excluded cases and controls were similar, it is unlikely that these differences led to bias. However, generalizations from this study should be limited to veterans who are demographically similar to the enrolled population.

Observation bias was improbable because identification of veterans was done blindly using military records. To control potential confounding, we excluded high-risk women and, when possible, used multivariate techniques to adjust for other variables. In addition, we compared Vietnam veterans to other veterans in order to control for factors related to entry into military service. However, since we lacked specific data on paternal exposures and conditions, it is possible that confounding was not completely controlled.

Studies have been conducted among North Vietnamese military veterans who were possibly exposed during the Vietnam war.[15,16] Positive associations were generally found but their validity is difficult to assess since they have never been published but have only been described briefly by scientists who attended the 1983 International Symposium on the Effects of Phenoxy Herbicides.

In contrast, two case-control studies conducted among Australian Army and US Vietnam veterans found no overall increase in the risk of major malformations (ORs 1.03 and 0.97, respectively).[4,5] The Centers for Disease Control study found that US Vietnam veterans with greater estimated opportunities for Agent Orange exposure had stable increases in the risk of fathering infants with spina bifida (but not anencephaly), cleft lip with or without cleft palate, congenital neoplasms, and

coloboma.[5] The Australian study found that Army veterans had unstable increases in the risk of fathering children with ventricular septal defects and Down's Syndrome.[4]

Preliminary results from a retrospective cohort study among the US Air Force personnel who conducted the aerial herbicide spraying missions in Vietnam revealed an elevation in the risk of fathering infants with major and minor birth defects combined (OR: 1.3) that was due primarily to minor skin anomalies. Unlike our study, the skin anomalies reported among the Air Force children were mainly birthmarks and other skin discolorations. Investigators also observed no increase in the risk of stillbirths but a 3.8-fold increase in the risk of neonatal deaths. Recall bias cannot be ruled out in the Air Force data since they were based solely on interviews; collection of birth records to verify these associations is currently underway.[6]

Another US study further examined reproductive and other health outcomes among a cohort of Army veterans. At interview Vietnam veterans were more likely to report that they fathered a child with a birth defect than were non-Vietnam veterans (OR: 1.3, 95% CI:1.2, 1.4). In contrast, a sub-study using only diagnoses recorded in hospital records found similar rates of major, minor and "suspected" birth defects among Vietnam and non-Vietnam veterans (OR's: 1.1, 1.0, 0.9, respectively).[7]

In summary, current and previous study results are not in agreement concerning the risk of major malformations among Vietnam veterans. No consistent pattern of defects has emerged. We conclude that large studies, preferably with individual herbicide exposure data, would be needed to clarify the risk of late adverse pregnancy outcomes among Vietnam veterans overall as well as the subgroup of veterans who were exposed to Agent Orange.

ACKNOWLEDGMENTS

The authors gratefully acknowledge Suzanne Griffith and Lisa Samuelson for their help with data collection, Amy Cohen for her expert programming assistance, and the Office of the Assistant Secretary of Defense, the National Personnel Records Center, the Massachusetts Adjutant General's Office, and the Massachusetts Office of the Commissioner of Veterans' Services for making available the military service data.

Lyme Disease in New Jersey Outdoor Workers: A Statewide Survey of Seroprevalence and Tick Exposure

MICHAEL D. GOLDSTEIN, MD, MPH, BRIAN S. SCHWARTZ, MD, MS, CRAIG FRIEDMANN, MD, BARBARA MACCARILLO, RN, MAUREEN BORBI, RN, AND ROSEMARIE TUCCILLO, BA

Abstract: To evaluate the spread of Lyme disease in New Jersey, we conducted a statewide cross-sectional study of Lyme disease seroprevalence in a high-risk occupational group of outdoor employees. Of the 689 employees who participated in the study, 39 (5.7 percent) were positive for antibody to *B. burgdorferi*, the causative agent of Lyme disease. Seroprevalence varied markedly by county; unexpectedly high seroprevalence rates were found in several northern counties (Sussex, Hudson, and Hunterdon). Furthermore, some southern counties (Atlantic, Cape May, and Ocean) with large tick populations (as measured by self-reported exposure to ticks) had low seroprevalence rates which were inversely correlated with self-reported preventive practices. These data suggest that lyme disease, as measured by seroprevalence of antibody to *B. burgdorferi*, may be spreading beyond the southern portion of the state where it had been previously well documented and that preventive behaviors may play an important role in minimizing the risk of the disease. (*Am J Public Health* 1990; 80:1225–1229.)

Introduction

The incidence of Lyme disease is increasing in many areas of the United States. The disease is caused by the spirochete *Borrelia burgdorferi* and transmitted by the *Ixodid* ticks. Early reports of the disease in the United States were from Connecticut in the late 1970s[1] but the disease is now a public health concern in the surrounding states (New Jersey, New York, and Massachusetts) as well, and has been reported in at least 43 states.[2]

A series of investigations in New Jersey were performed during the period 1978–82 by Bowen and Schulze, *et al.*[3–7] They found that, of 117 reported Lyme disease cases during the period, 48 percent (57) had occurred in one centrally located county (Monmouth). Almost all cases (98 percent) had occurred in the central and southern portions of the state.[5] Furthermore, the statewide distribution of *Ixodes dammini* correlated with the location of reported cases and revealed a high density of *Ixodes dammini* in the southern two-thirds of the state and a particularly high concentration in Monmouth County. It should be noted that while *Ixodes dammini* is the primary vector of Lyme disease in the northeast United States, the causative agent, *B. burgdorferi* has been identified in a number of species of ticks including *Amblyomma americanum*, and *Dermacentor variabilis*.[8]

In an attempt to further evaluate the spread of Lyme disease in New Jersey, we conducted a statewide cross-sectional study of Lyme disease seroprevalence in a high-risk occupational group. We measured: 1) seroprevalence of antibody to *B. burgdorferi*, 2) self-reported tick exposure and, 3) self-reported preventive practices among outdoor workers in the Natural and Historic Resources divisions of the New Jersey Department of Environmental Protection.

Methods

Study Population

The New Jersey Natural and Historic Resources (NHR) Section consists of four divisions: Parks and Forestry; Coastal Resources; Green Acres; and Fish, Game and Wildlife. Employees work primarily in outdoor jobs in a variety of habitats including mountainous regions, grass lands, forests, and shoreline. Geographically, they are distributed across the state from Stokes State Forest on the state line with New York in the north to Cape May County across the bay from Delaware in the south. During October 1988, we conducted a Lyme disease evaluation of employees at 12 different sites across the state on 15 dates. The summer months of May through August are the highest risk months and antibody seroconversion generally occurs three to six weeks after infection.[9] Participation was voluntary and all participating employees gave informed consent. A total of 689 (69 percent) of an estimated 1,000 eligible employees participated in the study.

Data Collection

The evaluation consisted of venipuncture for a serum specimen and administration of a questionnaire. Whole blood specimens were centrifuged and then divided into as many as five equal aliquots. An initial fresh specimen was sent to a commercial laboratory for immunofluorescent antibody (IFA) titer to *B. burgdorferi*. A titer of 1:128 or greater was reported as positive by the laboratory. The remaining samples were frozen and then after the initial fresh specimen results were reported, all positives and a random sample of the negatives were sent to as many as three other laboratories for analysis. Samples were analyzed at one department of health laboratory and at two university research laboratories by IFA in one case and enzyme linked immunosorbent assay (ELISA) in the other two. To be defined as positive for antibody to *Borrelia burgdorferi* in the study, the worker had to have at least two positive tests in two independent laboratories.

All employees participating in the study completed a self-administered questionnaire. The administration of the questionnaire was supervised by the authors and checked for accuracy after completion. Study variables included demographic data, counties of work and residence, self-reported measures of tick exposure, and frequency of performance of six behavioral practices of potential benefit in minimizing the risk of *B. burgdorferi* infection.

For purposes of data analysis and description, the counties of the state have been defined as northern or southern based on a line which cuts New Jersey geographically in half. The line runs from the lower border of Mercer

From the Center for Occupational Medicine, New Jersey Department of Environmental Protection Trenton (Goldstein, Maccarillo, Borbi, Tuccillo); the Clinical Epidemiology Unit, Section of General Internal Medicine, University of Pennsylvania, Philadelphia (Schwartz); and the Occupational Medicine Program, Columbia University School of Public Health, New York City (Friedmann). This paper, submitted to the Journal October 11, 1989, was revised and accepted for publication April 2, 1990.

County through the middle of Monmouth County (Figure 1). Since the dividing line runs through Monmouth County, and because that county is unique in that it has a particularly well documented history of elevated Lyme disease risk, Monmouth will be discussed separately and not included with the northern or southern groupings.

Results

Seroprevalence

Statewide: A total of 689 employees of the NHR divisions of the NJ Department of Environmental Protection participated in the study. Thirty-nine employees (5.7 percent) had at least two positive tests for antibody to *B. burgdorferi*, the causative agent of Lyme disease. There were no differences in seropositivity based on years of outdoor state employment. The 39 seropositive subjects were found to have a mean (SD) of 16.5 (28.9) years of outdoor state employment while the seronegatives had a mean (SD) of 19.0 (28.0) years. There were no important differences based on job title or primary job habitat.

Geographic Distribution: Figure 1 displays the distribution of seropositives based upon county(s) of employment (some employees worked in more than one county on a regular basis). Seroprevalence ranged from a low of zero percent in four counties (Bergen, Camden, Gloucester, and Union) to highs of 6.5, 7.2, 7.8, and 18.5 percent in Hunterdon, Sussex, Monmouth, and Hudson counties, respectively. The 20 percent seroprevalence found in Essex County is based upon only five workers sampled.

Self-Reported Tick Exposure

Statewide: Based on self-reports from the 689 employees who participated in the study, the workers reported a mean (SD) of 3.5 (7.6) and a median of 1.0 tick bites (ticks embedded in the skin) during the past year. The number of ticks removed from skin or clothing per week (during May–August 1988) on the primary job (some employees had other non-DEP jobs) was reported as a mean of 2.5 (SD ± 5.4) and a median of 2.0

Geographic Distribution: Figure 2 displays the mean number of tick bites over the past 12 months by county of employment. The mean yearly bite totals ranged from less than 1.5 in Hudson, Sussex, Union, and Warren counties to greater than 7.5 in Essex, Cumberland, and Camden counties. The mean number of ticks removed from skin or clothing per week on the primary state job by county of employment ranged from less than 1.5 ticks per week in Bergen, Passaic, Sussex, and Union counties to greater than 4.0 ticks per week in Burlington, Cape May, Cumberland, and Salem counties.

Preventive Measures: Self-reported behavioral practices are displayed in Table 1 on a statewide basis and by selected counties in Table 2. These behaviors were performed more frequently on the job than in non-occupational settings. Additionally, although workers frequently checked themselves for ticks, a minority of workers reported the other behaviors. In an effort to account for the unexpectedly high seroprevalence rates found in three northern counties (Sussex, Hudson, and Hunterdon) we chose to compare the preventive behavior performance frequencies in these counties with the frequencies found in three southern counties with relatively low seroprevalence rates. Table 2 reveals that these preventive behaviors were performed more frequently by employees in Monmouth County and three selected southern counties (Atlantic, Ocean, and Cape May) than they were in the three northern counties (Sussex, Hudson, and Hunterdon). The results for the other northern and southern counties were similar to those for the selected northern and southern counties reported.

Discussion

To our knowledge, the present study is the first to investigate the seroprevalence of antibody to *B. burgdorferi* on a statewide basis.

Several studies have investigated the seroprevalence or the seroconversion rate of populations residing or working in endemic areas. An early investigation in 1982 reported a one-year clinical Lyme disease cumulative incidence rate of

1.1 percent in 1,364 residents and employees living on or around the grounds of Naval Weapons Station Earle in Monmouth County, New Jersey.[10] A 1984 study of 176 residents of a Fire Island, New York summer community revealed that 9.7 percent had serological evidence of exposure to the Lyme spirochete in the initial cross-sectional portion of the study.[11] A 1986 study of long-term residents on Great Island, Massachusetts reported a seroprevalence of 8 percent among 121 asymptomatic residents.[12] More recently, an evaluation of 190 residents living within 5 kilometers of a nature preserve in Ipswich, Massachusetts from 1980–87 revealed a Lyme disease attack rate of 35 percent based on a clinical case definition.[13] Seventy-three percent of those with clinical disease and 23 percent of all residents tested were found to be seropositive for *Borrelia burgdorferi*-specific antibody. A 1982 comparison of outdoor versus indoor workers at Naval Weapons Station Earle revealed a five-fold higher cumulative incidence rate for Lyme disease among outdoor workers.[3] Finally, a recent study by Smith, *et al*, of 414 outdoor workers in southeastern New York State revealed a Lyme disease seroprevalence of 6.5 percent among these employees.[14] This was 5.9 times higher than the seroprevalence of a comparison group of anonymous blood donors from the same region.

It should be noted that participation in the study was voluntary and therefore unequal participation by county is a potential source of bias. Rates of participation on a county-by-county basis were not possible to determine. We did, however, find that the main determinant of participation was whether or not the employee's primary work location was one of the screening sites. These sites included an equal number of randomly distributed northern and southern locations. Job duties were similar in all the counties and the vast majority of all subjects statewide had not previously been tested. Therefore we feel it is unlikely that there was any specific county characteristic which resulted in a differential degree of study participation.

Our statewide seroprevalence of antibody to *B. burgdorferi* (5.7 percent) in a high-risk group of outdoor workers is comparable to the 6.5 percent seroprevalence found by Smith, *et al*, in New York State. When examined on a county-by-county basis, however, there were some unexpected findings. Earlier studies by Bowen and Schulze of Lyme disease distribution in New Jersey (1978–82) had reported a large number of case reports, as well as a high density of *Ixodes dammini*, in Monmouth County and the southern half of the state. Their results revealed a paucity of cases and ticks in the northern half of the state.[3–7] The present study revealed that one of five counties with seroprevalences greater than the statewide mean of 5.7 percent was Monmouth County and the others—Sussex, Hunterdon, Hudson, and Essex—were all counties in the northern half of the state (Figure 1). The Essex finding can be discounted because of a very small denominator (n = 5) but denominators for the other counties were much larger (n = 27 to 129). Similar (unpublished) analyses of distribution based on county of residence revealed seven counties with seroprevalence rates greater than the statewide mean. One was Monmouth, but again five of the remaining six (Sussex, Hudson, Middlesex, Somerset, and Mercer) were in the northern half of the state.

The preponderance of northern counties with elevated seroprevalence was not matched by an increased level of self-reported tick exposure in these counties. In fact, as displayed in Figure 2, the vast majority of counties with tick exposures greater than the statewide mean were southern counties; for "total tick bites in the past year," seven out of eight were southern counties. Similarly for "ticks removed from skin or clothing per week on primary job," eight out of 10 were southern counties.

In three southern counties, where seroprevalence was low but tick exposure was high, the employees performed the preventive measures on a "frequent" basis more often than their colleagues statewide (based on mean results from all 689 employees). In Monmouth County, the traditional hotbed of Lyme disease in New Jersey where only a moderately elevated seroprevalence rate was found, the employees also reported performance of preventive measures at a greater frequency than the statewide mean. Finally in three northern counties with relatively high seroprevalence rates and relatively low tick exposure, the employees were performing preventive measures less frequently than other employees statewide.

These findings suggest that the performance of preventive behaviors may reduce the risk of exposure to *B. burgdorferi*. These results do not establish a causal relationship but do merit further investigation. It may be postulated that there has been a relatively recent spread of infected ticks to the northern counties and, although their numbers are still not great, the northern ticks are feeding on a more susceptible human population.[13] The well-publicized history of Lyme disease in the southern counties may have led to a better educated public in these counties and therefore a greater awareness of ticks and appropriate risk reduction behaviors. It is possible that a certain number of individuals from southern counties where Lyme disease had been better publicized responded with expected behavior rather than

*Statewide mean percent for frequent performance (usually or always)

actual behavior leading to a potential source of bias. This differential Lyme disease awareness may have also resulted in an overreporting of tick exposure in the southern counties and a relative underreporting in the northern counties. A comprehensive statewide study of tick concentrations would help to resolve this last possibility. However, some limited statewide data (Schulze TL: unpublished data) suggest that tick concentrations are much lower in the northern part of the state and that differential reporting of tick exposure is, in fact, not likely to be the explanation for the observed differences in seroprevalence.

In summary, the findings suggest that Lyme disease, as measured by seroprevalence of antibody to *B. burgdorferi*, appears to be spreading beyond Monmouth County and southern portions of the state where it had been previously identified. This spread into the northern counties may not necessarily be solely from southern New Jersey but could also reflect the spread of disease from bordering Orange and Rockland counties in New York. Unexpectedly high seroprevalences were found in several northern New Jersey counties (Sussex, Hudson, and Hunterdon). These high seroprevalence rates in regions of relatively low tick exposure, coupled with low rates (Atlantic, Ocean, and Cape May) and surprisingly moderate rates (Monmouth) in areas of higher tick exposure may be related to preventive behaviors. These results suggest that simple preventive behaviors may have a significant impact on minimizing the risk of Lyme disease.

ACKNOWLEDGMENTS

The authors would like to thank John Fleming and Pat Cummins of the NJ Department of Environmental Protection, Geographic Information Systems Unit for their invaluable help in preparation of the county maps; and Assistant Commissioner Helen Fenske and Deputy Assistant Commissioner James Hall, as well as all the employees of the DEP Natural and Historic Resources division, without whose enthusiastic support this project would not have been possible.

This work was supported by the New Jersey Department of Environmental Protection and the Andrew W. Mellon Foundation (Dr. Schwartz).

Evaluating the Impact of Municipal Water Fluoridation on the Aquatic Environment

JOHN W. OSTERMAN, MD, ScD

Abstract: Although highly beneficial for dental health, low concentrations of fluoride in environmental waters may be toxic to several organisms. In an era of heightened public awareness about the environment, this may lead city officials to withhold implementing water fluoridation for environmental reasons. This paper presents a mass balance approach to evaluate this perceived risk. Generally speaking, fluoridated water loss during use, dilution of sewage by rain and ground water infiltrate, fluoride removal during secondary sewage treatment, and diffusion dynamics at effluent outfall combine to eliminate fluoridation-related environmental effects. In Montreal, water fluoridation would raise average aquatic fluoride levels in the waste water plume immediately below effluent outfall by only 0.05–0.09 mg/l. Downstream, these changes would be only 0.02–0.05 mg/l at 1 km, and 0.01–0.03 mg/l at 2 km below outfall. Overall river fluoride concentrations theoretically would be raised by 0.001–0.002 mg/l, a value not measurable by current analytical techniques. All resulting concentrations would be well below those recommended for environmental safety and would not exceed natural levels found elsewhere in Quebec. A literature review did not reveal any examples of municipal water fluoridation causing recommended environmental concentrations to be exceeded, although excesses occurred in several cases of severe industrial water pollution. (*Am J Public Health* 1990; 80:1230–1235.)

Introduction

The beneficial effects of water fluoridation for human health are widely recognized.[1–3] Optimally fluoridated drinking water significantly reduces dental caries in both children and adults.[2–5] Fluoride may also reduce the incidence of osteoporosis and hip fractures, although the evidence is controversial.[6–8] No side effects occur.[1–3] Although the prevalence of mild dental fluorosis may increase, the esthetic effects of this mild tooth whitening are greatly outweighed by the improved esthetics of fewer decayed, missing, and filled teeth.[9] By far the most cost-effective intervention in dentistry,[10] optimally fluoridated water is provided in more than 10,000 North American communities and in countries around the globe.[11–13]

The toxic environmental effects of fluorides are also well documented, however. Airborne fluoride pollution from industrial sources may cause severe effects in plants by inhibiting photosynthesis, chlorophyll production and carbohydrate metabolism, with resulting defoliation or death.[14–16] Most plants accumulate fluoride which may lead to bony and dental fluorosis, lameness, arthritis, and other symptoms in wild and domestic herbivores foraging downwind from fluoride air pollution sources.[17]

As a water pollutant, elevated concentrations of fluoride may affect a number of organisms, including fish, amphibians, insects, snails, shellfish, protozoa, and some aquatic plants.[18] Fresh water fish, especially rainbow trout and other trout species, appear to be particularly sensitive and may show growth and behavioral changes, decreased survival, and prolonged hatching time when exposed to moderate levels.[19] Under negligible water hardness conditions, lethal effects for rainbow trout may occur at fluoride concentrations as low as 2.7–4.7 mg/l[20] and one undocumented observation reported delayed hatching of trout eggs at 1.5 mg/l.[21] Small amounts of calcium carbonate found in soft or moderately hard water, however, greatly reduce these effects,[22] as do water hardness generally, alkalinity, the presence of metallic ions (particularly calcium and magnesium) and chloride.[22–24] Toxicity increases with water temperature, by increasing fish metabolism.[25]

To protect aquatic organisms, several authorities recommend an upper limit between 1.0 mg/l and 1.8 mg/l of fluoride for fresh water systems.[18,26–28] Others feel that the environmental literature on fluoride toxicity is incomplete. They recommend that levels protecting drinking water (generally 1.2 to 2.0 mg/l) also be used to protect the environment, arguing that detectable effects occur in humans at lower concentrations than in other species.[29–32] Nevertheless, some states allow concentrations as high as 5–10 mg/l if the contaminated water is not subsequently used for human consumption.[33] No effluent standards exist.

Industrial waste and municipal sewage may add to the fluoride which is naturally present in all surface water.[33] In an era of heightened public awareness about environmental issues, concerns of public interest groups may lead city officials and politicians to withhold water fluoridation for environmental reasons, as occurred in Montreal in 1988.

To evaluate the environmental impact of water fluoridation, this paper uses a mass balance (material balance) approach to develop a series of mathematical equations which describe the fate of fluoride added to drinking water in a typical municipal water management system. In this approach, the ionic mass of fluoride entering the aquatic system from all sources is calculated, its distribution followed, and its fate examined; by balancing fluoride inputs and outputs, intervening concentrations and changes may be determined. This approach, widely used in environmental impact analyses,[34] is analagous to the study of physiologic or pharmacologic agents in living organisms.

The equations described below may be applied to readily available data from relevent water authorities to predict potential fluoridation-related changes in environmental waters receiving municipal effluent. These changes may be compared to natural variations in local ambient fluoride concentrations, the scientific literature concerning fluoride toxicity to aquatic organisms, and to recommendations from

scientific and government agencies. The city of Montreal is presented as an example.

Methods

Fate of Fluorides in Municipal Water Systems

For most municipal water management systems, drinking water is drawn from a lake, river, or subterrain well and is pumped to a purification plant. There it may undergo aeration, flocculation, coagulation and sedimentation, filtration and be disinfected with ozone or chlorine dioxide. Usually a small amount of residual chlorine is maintained in the drinking water to avoid bacterial regrowth in the distribution system. Ambient fluoride concentrations are generally measured in the final stages of water purification. Fluoride is then added to obtain optimal levels, between 0.7 and 1.2 mg/l depending on climatic conditions. Although several fluoride-containing compounds may be used, all dissociate on admixing, thereby liberating free fluoride ion ($F-$).[35] Occasionally, when drinking water sources contain high concentrations of fluoride, the water may be "defluoridated" to optimal levels by one of several methods.[36]

Drinking water is distributed to a variety of residential, industrial, commercial, and municipal clients. Waste water from all these sources is collected by the city sewer system and is transported to the sewage treatment plant. Industrial and human wastes increase sewage fluoride levels. Some fluoride is lost, however, when drinking water is used to water gardens, wash cars, fill pools, extinguish fires, etc. Infiltrating ground water, underground streams, and rain may add to sewage flow and cause considerable dilution.

Primary sewage treatment removes suspended solids and phosphates by screening, filtration, flocculation, coagulation and sedimentation. Several common processes using iron salt coagulation, lime, or activated alumina may remove fluoride at high concentrations; however, these effects are minor at the low concentrations of fluoride found in municipal sewage.[36,37] After initial treatment, waste water undergoes secondary (biological) treatment in order to destroy unwanted organisms and reduce nitrogen levels and biochemical oxygen demand (BOD). The microorganisms present in most secondary treatment systems absorb large quantities of fluoride and may reduce fluoride concentrations in effluent by up to 50 percent.[38,39] Effluent may then undergo further disinfection with chlorine before discharge.

Effluent is generally discharged from an outfall pipe at a lake, river, or ocean bottom. The warmer effluent rises quickly to the surface creating physical turbulence and an immediate dilution which may be as high as 5–15 times. If natural dilution is low, a diffusion apparatus may be installed at effluent outfall which distributes effluent evenly over a wide area to ensure similar dilution levels.[40] Natural currents then carry the waste water downstream, creating a waste water "plume" and secondary dilution over several miles.

Mathematical Equations Evaluating Fluoridation Impact

From this overview of the fate of fluorides used in water fluoridation, mathematical equations may be derived to estimate the impact of fluoridation on the aquatic environment downstream of municipal sewage outfall. Terms used in these equations are defined in Table 1.

Global Impact

An estimate of global environmental impact may be obtained by comparing the fluoride needed to optimally fluoridate drinking water to the amount naturally present in the aquatic system receiving municipal effluent. Adjusted fluoride equals the difference between optimal and pre-existing drinking water fluoride concentrations (ΔF_M) multiplied by the rate per unit time of drinking water production (Q_M). Environmental fluoride equals the sum of fluoride naturally present in drinking water ($F_{M1}Q_M$) and fluoride naturally present in the waters receiving municipal effluent ($F_{E1}Q_E$). Thus,

TABLE 1—Definition of Symbols

*Fluoride Concentrations**		
F_M	=	fluoride concentration in municipal drinking water
F_R	=	fluoride concentration in raw sewage
F_T	=	fluoride concentration in treated sewage
F_E	=	fluoride concentration in environmental water receiving municipal effluent
F_X	=	fluoride concentration in waste water plume at point X, downstream from effluent outfall site
Flow Rates		
Q_M	=	flow rate (production) of municipal drinking water
Q_S	=	flow rate of sewage at treatment plant
Q_E	=	flow rate of environmental water receiving municipal effluent
Portions		
P_M	=	portion of municipal drinking water destined for sewers
P_D	=	portion of sewage originating as drinking water
PE_X	=	portion of environmental water affected by waste water plume at point X
Diffusion Factor		
DF_X	=	a unitless number describing cumulative dilution occurring in the waste water plume from effluent outfall to point X downstream

*Fluoride concentrations before and after fluoridation (see text) are respectively indicated by subscripts 1 and 2.

$$\frac{\text{Municipal F}}{\text{Environmental F}} = \frac{\Delta F_M Q_M}{F_{E1}Q_E + F_{M1}Q_M} \quad (1)$$

If Q_M is very small relative to Q_E, in the case of a small municipality discharging into a large river, then Equation 1 simplifies to:

$$\frac{\text{Municipal F}}{\text{Environmental F}} = \frac{\Delta F_M Q_M}{F_{E1}Q_E} \quad (2)$$

Multiple municipalities and river systems may be considered in an additive fashion using the general formula:

$$\frac{\text{Municipal F}}{\text{Environmental F}} = \frac{\Sigma_i \Delta F_{Mi} Q_{Mi}}{\Sigma_i F_{E1i} Q_{Ei} + \Sigma_i F_{M1i} Q_{Mi}} \quad (3)$$

The change in environmental fluoride concentrations due to fluoridation (ΔF_E) may be obtained by dividing the fluoride added to drinking water by the sum of municipal and receiving water flow rates.

$$\Delta F_E = \frac{\Delta F_M Q_M}{Q_E + Q_M} \quad (4)$$

In a multiple city or river situation, this relationship becomes:

$$\Delta F_E = \frac{\Sigma_i \Delta F_{Mi} Q_{Mi}}{\Sigma_i Q_{Ei} + \Sigma_i Q_{Mi}} \quad (5)$$

Obviously, the post-fluoridation concentration in water downstream from municipal sewage outfall equals the sum of the calculated change and the pre-existing concentration. The ratio of these two values ($\Delta F_E/F_{E1}$) is identical to Equation 1.

While conceptually simple, these models overestimate the real effects of fluoridation on the environment by assuming that all drinking water is discharged as waste, by excluding the effects of sewage treatment, and by discounting eventual fluoride deposition into sediments. Moreover, estimates from these models are valid only at some theoretical point downstream where municipal effluent and receiving waters have become thoroughly mixed.

The first of these objections may be overcome by including in the numerator of Equations 1–5 only the percentage of drinking water which is eventually discharged as effluent (P_M). Thus, for example, Equation 1 would be corrected to:

$$\frac{\text{Municipal F}}{\text{Environmental F}} = \frac{\Delta F_M Q_M P_M}{F_{E1}Q_E + F_{M1}Q_M} \quad (6)$$

Local Impact

To estimate fluoridation-related changes in fluoride concentrations in the waste water plume downstream from municipal effluent outfall, the effect of sewage treatment must first be evaluated by comparing fluoride concentrations in treated (F_{T1}) and raw (F_{R1}) sewage. The ratio of these values (F_{T1}/F_{R1}) shows the portion of fluoride remaining after sewage treatment and is not affected by fluoridation status.[38,39] The concentration of fluoride in post-fluoridation treated municipal effluent (F_{T2}) may then be estimated.

$$F_{T2} = F_{T1} + \frac{\Delta F_M P_D F_{T1}}{F_{R1}} \quad (7)$$

P_D is the portion of sewage originating as drinking water and equals $Q_M P_M/Q_S$. From the rate of diffusion of waste water in the effluent plume (DF_X), the concentration of fluoride in the plume (F_{X2}) may now be estimated at outfall and for points downstream.

$$F_{X2} = \frac{F_{T2} + F_{E1}(DF_X - 1)}{DF_X} \quad (8)$$

The change in fluoride concentration at any point downstream from outfall (ΔF_X) equals:

$$\Delta F_X = \frac{\Delta F_T}{DF_X} \quad (9)$$

Waste water is unequally distributed in the plume. Thus, diffusion, and DF_X, is greatest at the edge where effluent concentrations are least and, conversely, least at the center where concentrations are highest. Also, turbulence may create eddies of poorly diluted effluent at the outfall site, which disappear downstream. It should be noted that DF_X has a maximum value equal to flow in the receiving water (Q_E) divided by flow of municipal sewage (Q_S); generally this limit is important only when large volumes of effluent are discharged into small bodies of water.

The effluent plume affects only a portion of the receiving waters. This portion (P_X) at point "X" may be calculated as follows:

$$P_X = \frac{Q_S(DF_X)}{Q_E} \quad (10)$$

Results

An Example: The City of Montreal

Montreal's drinking water, serving 1,6 million people, is drawn from the St. Lawrence River, near the Lachine Rapids slightly upstream from the city, and is returned some 35 km downstream at Ile-aux-Vaches. From data provided by municipal, provincial, and federal agencies,[41–47] potential global changes in fluoride levels related to water fluoridation were estimated (Table 2). At the Lachine Rapids the daily water flow of the St. Lawrence averages 883 (range 659–1028) million cubic meters, and natural fluoride levels average 0.13 (range 0.11–0.17) mg/l. On average, therefore, 115 tonnes (tonne = 1000 kg = 2,204.6 pounds) of naturally present fluoride (theoretical range 73–175) flow past Montreal daily. Assuming all municipal drinking water eventually returns to the river, fluoridation would add an additional 1.93 tonnes to this water, or 1/60 (1.7 percent) of naturally occurring amounts. On average, however, only 57 percent of Montreal's drinking water returns to the river, making the additional fluoride load closer to 1.09 tonnes, or 1 percent of natural amounts. This additional charge is well within natural variations in fluoride concentration (±15 percent), river flow (± 16 percent), and fluoride ion mass (±37 percent). Overall, the average concentration of fluoride in the river downstream from effluent outfall would increase by 0.001–0.002 mg/l, a value which is not measurable by current analytical methods.

Excluding rain, Montreal produces an average of 2.4 million cubic meters of sewage per day, of which 42 percent originates as unfluoridated drinking water, 2 percent as fluoridated drinking water from neighboring suburbs, and 56 percent from infiltrating ground water. This latter value is very high, due to Montreal's island geography, and an old combined sewer system in one sector. Optimal fluoridation in Montreal would increase drinking water fluoride concentrations from 0.11–0.15 mg/l to 1.2 mg/l which would in turn increase the average concentration of fluoride in Montreal sewage by 0.45 ± 0.01 mg/l. Daily fluoride concentrations in

TABLE 2—Average Daily Water Flow and Fluoride Levels in the St. Lawrence River and Montreal Water Supplies, before and after Fluoridation (range in parentheses)

	Flow Rate ($m^3 \times 10^6$)	Fluoride Ion Concentration (mg/l)	Fluoride Ion Mass (metric tons)
St. Lawrence River	883 (659–1028)	0.13 (0.11–0.17)	115 (73–175)
Water supply before fluoridation	1.8 (1.5–2.2)	0.13 (0.11–0.15)	0.23 (0.16–0.33)
Water supply after fluoridation	1.8 (1.5–2.2)	1.2	2.16 (1.80–2.64)
Fluoride added to water supply	1.8 (1.5–2.2)	1.07 (1.05–1.09)	1.93 (1.64–2.31)
Fluoride added to waste water from water supply	1.02*	1.07 (1.05–1.09)	1.09 (1.02–1.11)

*Range not available

Montreal sewage average 0.34 ± 0.07 mg/l (mean ± SD) and range from 0.22 to 0.58 mg/l.[45] Thus, after fluoridation, concentrations in Montreal sewage would become 0.79 ± 0.08 mg/l (mean ± SD) and range from 0.66 to 1.04 mg/l. Because Montreal sewage does not undergo biological treatment, little or no fluoride removal occurs at the sewage treatment plant.

The diffusion of Montreal's waste water in the St. Lawrence river was measured in 1983 as part of a feasibility study for the new municipal sewage treatment plant.[46] At sewage outfall a minimum initial diffusion factor of 5 occurred at the center of the waste water plume, and initial diffusion averaged 15 over the plume's entire cross-sectional area. After adjusting for current modifications which will increase outfall capacity and thereby decrease diffusion slightly, an average increase of 0.05 mg/l in fluoride concentration would be predicted across the plume immediately below effluent outfall (Table 3) and an average increase of 0.09 mg/l at the plume's center (Table 4). The plume's average concentration immediately below outfall would be 0.20 mg/l and the average level in the plume center at outfall would be 0.26 mg/l. Given known variations of fluoride ion concentrations in Montreal's sewage, the greatest daily average concentration expected would 0.34 mg/l at the outfall center. These values would decrease rapidly downstream. At 1 km from outfall an increase of only 0.02–0.05 mg/l would be expected. The predicted change at 2 km would be only 0.01–0.03 mg/l and would affect only 3.5–6.3 percent of the river.

Discussion

Using a mass balance approach, mathematical equations may be derived to evaluate the environmental impact of fluoride added to optimally fluoridate municipal water supplies. Generally, it will be shown that fluoridation has little impact on the surrounding aquatic environment. Some fluoride is lost when drinking water is used to water lawns, fill pools, etc; this usually ends up in the soil which may already contain large amounts (100–300 ppm).[3,33] Although fluoride concentrations in the sewer system may increase with the addition of industrial and human wastes, they are diluted by rain and infiltrated ground water. Up to 50 percent of fluoride may be removed during secondary sewage treatment. Initial diffusion rapidly dilutes the remainder at the effluent outfall site. Secondary diffusion causes further reductions downstream. Eventually, the remaining fluoride is incorporated into river sediments, or carried to the ocean which already contain large amounts (1.2–1.4 mg/l).[33] Any toxicity from this residual fluoride would be severely inhibited by other substances present in surface and waste waters, notably water hardness, calcium ion, and chloride.[22–24]

TABLE 3—Estimated Average Daily Fluoride Concentrations (mg/l) across Effluent Plume before and after Municipal Water Fluoridation in Montreal (range in parentheses)

Distance from Outfall (km)	Diffusion Factor*	Concentration before Fluoridation	Concentration after Fluoridation	Change	Portion of River Affected %
0.3	10	0.15 (0.12–0.21)	0.20 (0.16–0.26)	0.05	2.0

TABLE 4—Estimated Average Daily Fluoride Concentrations (mg/l) at Effluent Plume Center before and after Municipal Water Fluoridation in Montreal (range in parentheses)

Distance from Outfall (km)	Diffusion Factor*	Concentration before Fluoridation	Concentration after Fluoridation	Change	Portion of River Affected %
0.3	5	0.17 (0.13–0.25)	0.26 (0.22–0.34)	0.09	1.0
1	10	0.15 (0.12–0.21)	0.20 (0.16–0.26)	0.05	2.0
2	17	0.14 (0.12–0.19)	0.17 (0.14–0.22)	0.03	3.5

*Adjusted for current modifications to increase effluent capacity.

Montreal is a typical example. Due to its island geography, infiltrating ground water in the sewer system is probably greater than elsewhere, but this effect is offset by the lack of a secondary sewage treatment plant. Water fluoridation in Montreal would result in a slight increase in the fluoride concentration of the waste water plume directly below the effluent outfall. These changes would return to pre-existing levels within two kilometers. Global changes would not be measurable. Rain water, not included in this analysis, would reduce sewage concentrations and these findings even further.

The maximum predicted daily concentration at the center of the outfall site (0.34 mg/l) would be well below recommended levels for environmental safety,[18,26–32] and would be similar to natural levels occurring elsewhere. A survey in Quebec showed that average daily fresh water fluoride levels across the province varied from 0.07 to 0.24 mg/l and maximum levels of 1.7 mg/l occurred.[47] The average concentration in US rivers measured at 343 stations of the National Stream Quality Accounting Network in 1975 was 0.33 mg/l[48]; six streams in the southwest US had concentrations of 1.4 to 1.8 mg/l. Other investigators report that fluoride concentrations in US rivers average 0.2 mg/l and range from 0.0 to 6.5 mg/l.[49] In a polluted section of the Illinois River around Peoria, fluoride concentrations averaged 1.08 mg/l and ranged from 0.17 to 2.06 mg/l.[50] The source of the pollution was unspecified. Ocean concentrations range from 1.2 to 1.4 mg/l.[33] One result is that marine and estuarine organisms are relatively immune to the toxic effect of fluoride.[33,51]

The predicted increase of 0.45 mg/l in the fluoride concentration of Montreal sewage due to water fluoridation is similar to findings elsewhere. Fluoride levels in raw sewage from seven fluoridated Ontario communities contained 0.47 mg/l more fluoride than raw sewage from 11 non-fluoridated communities (0.96 vs 0.49 mg/l), and treated sewage differed by 0.33 mg/l (0.62 vs 0.29 mg/l).[38] For 56 California cities, raw and primary treated sewage from fluoridated communities contained an average of 1.80 mg/l (range 1.4–3.2) or 0.37 mg/l more fluoride than non-fluoridated communities (average 1.43; range 0.6–3.6 mg/l).[39] Both studies showed the important effects of secondary sewage treatment which reduced effluent fluoride concentrations by 35 percent in Ontario and by 56 percent in California in both fluoridated and non-fluoridated communities. In California, domestic waste accounted for far more sewage fluoride than water fluoridation.

The fate of fluoride in waste water from municipal and industrial sources has been evaluated by a number of researchers. In 1973, fluoridated Bozeman, Montana (population 20,000) discharged an average of 8.5 m^3/min of primary treated municipal effluent into the East Gallatin River (average flow: 146.7m^3/min). This raised average fluoride levels from 0.33 mg/l, nine meters above outfall, to 0.62 mg/l at 0.3 km downstream.[52] A maximum level of 2.0 mg/l was recorded. Natural fluoride levels were reestablished 5.3 km downstream. Another study at the same site found that fluoride concentrations quadrupled at effluent outfall but returned to natural levels 4 km downstream.[53] These changes were not considered to have any effect on the environment.[29]

In 1977, fluoridated Minneapolis-St. Paul produced effluent at the rate of 9.6 m^3/sec with a fluoride concentration of 1.21 mg/l, which was added to the Mississippi River (flow rate 279 m^3/sec). Water collected 10 air miles below outfall contained the same fluoride concentration as that collected upstream from the sewage disposal plant.[54]

In 1986, Kudo, *et al*,[55] evaluated fluoride concentrations along four small rivers in an industrialized area of the French Alps near unfluoridated Grenoble. This city (population 350,000) added about 1.8 tonnes of fluoride daily in untreated sewage to the Isere River (flow rate 300 m^3/sec) which increased fluoride concentrations from 0.19 mg/l above the city to 0.26 mg/l some 70 km downstream. This study underlined the importance of industrial water pollution sources. On the small Arc River (flow rate 50 m^3/sec) fluoride concentrations increased from 0.13 mg/l to 0.62 mg/l over a 50 km portion during which it received industrial effluents from three aluminum factories, a factory producing silica, and a factory producing phosphates. Severe fluoride-containing air pollution from these companies had destroyed much of the area's vegetation.

In another study underlining the importance of industrial water pollution, Martin and Salvadori[56] found that industrial effluents from a fluorophosphate fertilizer plant in Rouen, France increased fluoride concentrations in the Seine River from 0.25 to 2.0 mg/l which eventually fell to 0.47 mg/l many miles downstream. Fluoride discharge was estimated to be 37 tonnes per day, a quantity which would fluoridate a city 20 times the size of Montreal!

In conclusion, by using a mass balance approach, fluoridation-related changes in environmental concentrations of fluoride may be estimated from knowledge of municipal water management systems and data which are usually readily available from appropriate water authorities. Generally speaking, these changes will be minimal and, except when accompanied by serious industrial pollution, will remain below toxic levels recorded in the literature and recommendations by scientific authorities for the protection of the environment and human health.

Crop Duster Aviation Mechanics: High Risk for Pesticide Poisoning

ROB MCCONNELL, MD, A. FELICIANO PACHECO ANTÓN, MD, AND RALPH MAGNOTTI, PHD

Abstract: A cross-sectional medical survey was conducted among 63 Nicaraguan aviation mechanics exposed to organophosphate and other toxic pesticides. Thirty-one (49 percent) reported having been acutely poisoned on the job. Also, seven of 14 novice mechanics, with less than one year on the job, reported that they had been poisoned. Thirty-eight (61 percent) had cholinesterase levels below the lower limit of normal, including three workers with levels less than 20 percent of the lower limit of normal. Risk factors for low cholinesterase included recent hire and recent poisoning. Workers did not use protective equipment, nor were there facilities for bathing on site. As a result of this survey, the government has prohibited the mixing and loading of pesticides at this airport and requires the washing of planes prior to maintenance work; coveralls and thin, pesticide impermeable gloves are to be issued to mechanics handling pesticide-contaminated parts. Closed system mixing and loading systems have been installed at satellite airstrips. (*Am J Public Health* 1990; 80:1236–1239.)

Introduction

Pesticide poisoning has been a major public health problem in Nicaragua for the last 30 years.[1] The country's principal traditional export is cotton, a crop which is sprayed up to 35 times a season with organophosphate insecticides for control of the boll weevil. Most of this spraying is done from crop dusting airplanes, and poisoning of highly exposed mixers and loaders at the airports and landing strips which service these airplanes has been recognized as a problem, both in Nicaragua and in the developed countries.[2]

The airplane mechanics who service these airplanes are a little studied population who have high exposure to pesticide-contaminated parts. To characterize exposure of these workers to pesticides and to assess any acute health effects, we evaluated mechanics at Nicaragua's largest crop dusting airport in late December 1987.

Methods

The 28 crop dusters owned by the six companies operating out of the airport made approximately 10 flights daily during the peak cotton spraying season (October 15 through early January). It was estimated that as much as 130,000 gallons were sprayed daily on flights originating from this airport, accounting for almost 30 percent of all pesticides sprayed in the department of Chinandega, the principal cotton growing region (Mario Pais, Ministry of Industry, personal communication). The mechanics were under pressure to do minor service and adjustment as quickly as possible, because the companies and pilots were reimbursed for each flight. There was little time to wash planes before minor maintenance. Most exposure was to the hands, since the manipulation of small mechanical parts was necessary for the routine work of changing pesticide filters and adjusting spray nozzles, and difficult to perform while wearing clumsy protective gloves.

The mechanics often did not know what pesticide was loaded in the plane they were servicing. One employee from each company, with responsibility for recording the pesticide used in each flight, characterized frequency of spraying as daily or as less frequently for the various pesticides used at the airport during the month prior to the study.

The 71 mechanics (all men) employed at the airport were invited for a questionnaire interview which asked about history of use of personal protective equipment, history of training regarding poisoning prevention, about previous poisoning, and about symptoms compatible with cholinesterase inhibitors (organophosphate and carbamate insecticides). The questionnaire asked about specific symptoms, such as headache, lightheadedness, blurred vision, lack of appetite, vomiting, stomach ache, and frequent spitting (sialorrhea). Erythrocyte cholinesterase is inhibited by organophosphate insecticides and is an early indicator of overexposure. It was measured using the Ellman assay (adapted for use with a new battery operated field kit), as previously described[3]:

> Briefly, 5 µl of blood was pipetted into a cuvette containing 200 µl of sample buffer containing Tris-HCl, Triton X-100 surfactant, and trace azide. Two ml of reagent solution containing acetylthiocholine iodide substrate, DTNB [5,5'-dithiobis(2-nitrobenzoic acid)] indicator, quinidine sulfate (to inhibit plasma cholinesterase), and phosphate buffer were added to the cuvette. The solution was incubated for three minutes and the change in absorbance noted between one minute and three minutes. The activity was adjusted for temperature and converted to international units. The results were not adjusted for hemoglobin. Forty-six healthy, unexposed male Nicaraguan health workers were sampled in order to establish a lower normal limit of 3.7 international units/minute/ml of blood. (This is the mean minus 1.65 standard deviations).
>
> Each worker was given the result of his cholinesterase assay at the time of the test.
>
> Confidence intervals for relative risk of low cholinesterase for various risk factors were calculated using the test-based method of Miettinen.[4] Multivariate analysis of mean cholinesterase was done using SPSS-PC.[5]

Results

All pesticides sprayed at the airport during the month prior to the survey are listed in the Appendix. Methamidophos, mephosfolan, methyl and diethyl parathion are all US Environmental Protection Agency (EPA) category I (acutely toxic) organophosphate insecticides. Chlorpyrifos (category II) and acephate (category III) are less toxic organophosphates. Cholinesterase depression reflects overexposure to these insecticides. Unfortunately, there are no good field methods for evaluating exposure to the non-

organophosphate pesticides, although there are several pesticides with chronic effects. A metabolite of chlordimeform was recently reported to be associated with a 73-fold excess risk of bladder cancer in exposed workers.[6]

Questionnaire

Sixty-three mechanics (88 percent) of the 71 who worked at the airport came to the health screening. Those who did not participate had been assigned temporarily to smaller satellite airports, were sick, or refused to participate. This is a relatively mature work force with an average of almost 10 years in the current job (Table 1). Nevertheless, there was a sizable proportion of novices (22 percent) with less than one year of experience, including one 11-year-old and one other worker under age 16, the minimum legal age for work with pesticides.[7] Almost half the workers reported having required medical attention for acute symptoms resulting from pesticide exposure at some time during work at the airport. Twelve (19 percent) of 63 reported that they were poisoned in the previous 12 months, and half of the 14 workers with less than one year of experience had been poisoned. Some older workers reported having been poisoned as many as seven times at the airport. The most common protective equipment used were boots (used by 14 percent), followed by coveralls (11 percent). No worker used protective gloves, a respirator, or protective glasses.

Cholinesterase Measurements

Thirty-eight (61 percent) of the 62 workers sampled had low erythrocyte cholinesterase levels (Table 1). The mean cholinesterase (3.1 international units [IU]/minute/ml blood) for all mechanics was less than the lower limit of normal of 3.7 IU. The lowest level recorded was 0.61 IU, one of three samples less than 20 percent of the lower limit of normal. That worker complained of headache and nausea, had pinpoint pupils and sialorrhea, and was diaphoretic, all of which responded to treatment with atropine sulfate.

We evaluated the following risk factors for depressed cholinesterase levels among these workers: recent poisoning, recent hire, no training about safe use of pesticides, less than daily change of clean work clothes, and symptoms compatible with organophosphate insecticide poisoning. In addition, the mean cholinesterase for workers with each risk factor was compared with the mean for all workers without the risk. Almost all workers poisoned in the previous year and almost all mechanics hired within the previous year had low cholinesterase values at the time of the screening (see Table 2). The presence or absence of more than two symptoms compatible with organophosphate insecticide poisoning was not reflected either in higher prevalence of low cholinesterase values (52 percent compared with 67 percent among those with two symptoms or less) or in lower mean cholinesterase levels.

Paradoxically, there was a higher prevalence of low cholinesterase among mechanics who reported a daily change of clean work clothes (87 percent) compared with mechanics who changed work clothes less often (53 percent).

There was a slightly lower prevalence of low cholinesterase levels among workers who had received some previous training about the safe handling of pesticides, and the mean cholinesterase level among workers who had received training (3.6 IU) was higher than among workers without any training (2.9 IU). However, this beneficial effect of training was confounded by the high exposure tasks of recently hired workers, who were also less likely to have received training. After controlling for a dummy variable representing recent hire (within the last year) in a multiple regression procedure, there was still a slight beneficial average effect on cholinesterase of having received training, but the effect was reduced (regression coefficient = 0.41 I.U.; 95% CI = −0.28, 1.13).

TABLE 1—Demographic Characteristics, History of Poisoning, and Cholinesterase Levels among Aviation Mechanics, Chinandega, Nicaragua, December 1987 (N = 63*)

Mean age (SD)	29.1 (10.1)
Mean duration (years) of employment (SD)	9.6 (8.2)
Number employed less than 1 year (%)	14 (22)
Number poisoned during employment at airport (%)	31 (49)
Number poisoned in previous 12 months (%)	12 (19)
Number poisoned in previous 12 months among mechanics with less than 1 year employment (%)	7/14 (50)
Number who have received pesticide safety training on current job (%)	16 (26)
Number with low erythrocyte cholinesterase (%)	38 (61)
Mean cholinesterase in international units/minute/ml blood (SD)	3.1 (1.3)

*Because of missing data the denominator varies slightly within this and subsequent tables.

Discussion

To our knowledge mechanics engaged in routine maintenance of crop dusters have not been studied previously. At this airport, they were at extraordinarily high risk for pesticide overexposure and for poisoning. Many of these workers reported being hospitalized for treatment, almost exclusively with signs and symptoms compatible with the cholinesterase inhibitors used at the airport. The high prevalence of cholinesterase depression is probably underestimated, because pre-exposure baseline levels of cholinesterase were not available. We therefore used a normal range based on inter-individual variability in cholinesterase. A more appropriate criterion for a low cholinesterase level is a drop of 30 percent from baseline, as recommended by the World Health Organization[8] and the US National Institute for Occupational Safety and Health.[9] Because the inter-individual normal range is almost a two-fold increase over the lower limit of normal, a decrease of well over 30 percent for someone with a high baseline cholinesterase level would still leave that person in the normal range in this study.

In workers with daily exposure to organophosphate pesticides, cholinesterase may be depressed without clinical signs and symptoms of poisoning.[10] The absence of association between symptoms and cholinesterase depression probably reflects the importance of the rate of decline in cholinesterase in producing symptoms.[2] A gradual inhibition of cholinesterase from continued low level exposure to organophosphates is less likely to produce symptoms than the same inhibition from a single large exposure. Our experience is not dissimilar to that reported in other studies, where symptoms sometimes have been found to be associated with chronic depression of cholinesterase and sometimes have not.[2,11–13]

It is likely that experienced workers tolerate the hazards of this job, because it is highly skilled and it pays well. In addition, the most hazardous work is done by the newly hired apprentice mechanics, many of whom do not return the following season. The anomalous increase in proportion of workers with low cholinesterase levels among those who changed to clean work clothes daily probably occurred because these young workers are in the dirtiest, most highly

TABLE 2—Mean Cholinesterase and Frequency of Low Cholinesterase among Aviation Mechanics by Selected Risk Factors, Chinandega, Nicaragua, December 1987

Risk Factor	Number with Low Cholinesterase (%)	Relative Risk (95% CI)	Mean Cholinesterase	Difference of Means (95% CI)
Poisoned in the previous year (N = 12)	11 (92)	1.7 (1.1, 2.6)	1.5 IU	−2.0 (−1.3, −2.7)
Not poisoned in the previous year (N = 50)	27 (54)		3.5 IU	
Less than 1 year in job (N = 14)	13 (93)	1.8 (1.2, 2.7)	2.0 IU	−1.4 (−0.7, −2.1)
One or more year in job (N = 48)	25 (52)		3.4 IU	
Has not received pesticide safety training at airport (N = 45)	30 (67)	1.5 (0.91, 2.5)	2.9 IU	−0.7 (−0.07, −1.3)
Has received training (N = 16)	7 (44)		3.6 IU	
Changes work clothes less often than daily (N = 47)	25 (53)	0.61 (0.40, 0.93)	3.2 IU	0.6 (1.3, −0.1)
Changes work clothes daily (N = 15)	13 (87)		2.6 IU	
More than 2 symptoms compatible with cholinesterase inhibitors (N = 23)	12 (52)	0.78 (0.50, 1.2)	3.0 IU	−0.1 (0.6, −0.8)
Two or fewer symptoms compatible with cholinesterase inhibitors (N = 38)	26 (67)		3.1 IU	

exposed jobs and are also more likely to need to change work clothes daily.

Pesticide hazards at this airport are characteristic of Central American and other developing countries where regulations or their enforcement are not adequately developed to protect workers from poisoning. Even for these highly trained workers at a work place of strategic importance for one of the country's principal sources of foreign exchange (cotton), there were no bathing facilities and the companies did not provide protective equipment. To have removed all mechanics with low cholinesterase levels from exposure would have severely compromised production at a time when it was critical to spray to control the boll weevil. Only workers with the lowest cholinesterase levels were automatically removed from production. Where possible, workers with less depressed levels were assigned to less exposed tasks, hardly an ideal solution, as all mechanic jobs involve potential pesticide exposure.

In addition, the pesticide multinationals have introduced products which are prohibited or severely restricted in the developed world, or which are not registered in developed countries and for which there is little health information available to national regulatory authorities. Although lowered cholinesterase levels reflect overexposure to, and poisonings result from, cholinesterase inhibitors, overexposure to cholinesterase inhibitors can be considered a marker for overexposure to other pesticides with chronic toxicity. Ethyl and methyl parathion are almost always mixed with the animal carcinogen toxaphene[15] in Nicaragua and were often applied with chlordimeform. Until recently, methyl parathion was involved in almost half of all poisonings reported in certain regions of the country.[11] The common practice of promoting the use of personal protective equipment (gloves and respirators) in a country where there is little personal protective equipment available, and where temperatures commonly reach 38 degrees centrigrade, is an inadequate solution to the problem of pesticide overexposure.

Nevertheless, Nicaragua appears to be taking the problem of pesticide health hazards seriously. In the past five years the government, with support from various nongovernmental organizations, has initiated programs to install closed systems (which mix and load the crop dusters without the workers having to directly handle the pesticide), and has initiated training programs to protect these workers. The Ministry of Health has prohibited the mixing and loading of pesticides at this airport; the airport is to serve as a base for storage, maintenance, and repair of previously washed planes. All mixing and loading is to be done at outlying satellite airstrips, where the closed mixing and loading systems have been installed. Although in practice this may be difficult to enforce, the Ministry's order (based on concern about contamination of ground water as well as worker health) is proving to be a useful tactic in forcing the companies to cooperate with remedial action. Coveralls have been distributed to all mechanics, and free laundry service is available to most of the mechanics working at the airport. Prior to the spray season in 1988, all mechanics were released from work for a two-day training program on safe handling of pesticides. A worker health and safety committee has been established and is being trained further in basic preventive measures and in emergency treatment of poisoning from cholinesterase inhibitors. Children under 16 years old are no longer employed at the airport, and funding has been obtained for a pilot program to evaluate a new, thin (but pesticide impermeable) glove to see if it can be used for the fine manipulation of parts by the mechanics. Perhaps the most important change which may result in decreased pesticide poisoning by these workers is the decreasing amount of land planted in cotton in Nicaragua. The result may be less demand for aerial spraying and less pressure to get the maximum production from each crop duster, making it possible to enforce the washing of each plane before any maintenance is done. Finally, despite strong objections by the cotton producing industry, the importation of chlordimeform was recently halted, and a new regulation gives a commission headed by the Ministry of Health the right to veto the importation of pesticides deemed to be dangerous to public health.

APPENDIX

Pesticides Used at Crop Dusting Airport, Chinandega, Nicaragua, December 1987

Pesticides with Long-term Health Effects

Chlordimeform** (metabolite is human bladder carcinogen)[6]
Methamidophos** (human delayed peripheral neurotoxin[14])
Toxaphene** (animal carcinogen[15])
Maneb/mancozeb** (animal carcinogen[9])

Other Pesticides Restricted or Prohibited in Other Countries[16]

Methomyl** Mephosfolan** Methyl** and diethyl* parathion

Other Pesticides not Registered in the US

Dominex** Bendocet** Jupiter**

Other Pesticides of Lesser Toxicity

Acephate**	Chlorpyrifos**	Deltamethrin**	Bacillus Thuringiensis**
Propargite**	Talstar*	Propiconazole*	Lambda Cyhalothrin**

*Sprayed at one or more companies during the 30 days prior to the study but not sprayed daily by any company.
**Sprayed daily by one or more companies during the 30 days prior to the study.

ACKNOWLEDGMENTS

We are grateful to Carmen Ibania Kuan, Donald Roque, Venancio Zapata and Fresia Morales Cabrera for their collaboration in the collection and analysis of data, and to Douglas Murray for his tireless work on behalf of pesticide health and safety in Nicaragua. We also appreciate the thoughtful comments of Dr. Philip Landrigan and Dr. Linda Rosenstock.

Health and Environmental Outcomes of Traditional and Modified Practices for Abatement of Residential Lead-Based Paint

MARK R. FARFEL, ScD, AND J. JULIAN CHISOLM, JR., MD

Abstract: We evaluated traditional and modified practices for abating lead-based paint in homes of children with blood-lead concentrations (PbB) > 1.4 μmol/L (> 29 μg/dl). Traditional abatement resulted in acute increases in: 1) lead contaminated house dust (generally 3 to 6-fold over pre-abatement levels, but at abated sites typically 10 to 100-fold); and 2) the PbBs of nearly half of the occupant children. Modified practices represented modest short-term improvement compared to traditional practices but were also inadequate. By six months, it was clear that neither form of abatement resulted in long-term reductions of PbB or house dust lead levels, leaving children at continued risk of excessive exposure to lead and permanent adverse neurobehavioral effects. Windows were found to be high sources of lead contaminated house dust. Recommendations are made for improved abatement practices including more complete abatement of window units and more effective clean-up to remove lead-bearing dust. Thirteen million US children live in lead-painted dwellings. Research is needed to identify abatement strategies that will be practical and well suited to the current understanding of low-level lead toxicity. (*Am J Public Health* 1990; 80:1240–1245.)

Introduction

Abatement of residential lead-based paint hazards was required more than 40 years ago in response to cases of symptomatic lead poisoning in children (generally, blood lead concentrations (PbB) > 3.86 μmol/L).* These cases were often associated with the ingestion of chips of lead-containing paint in dilapidated dwellings.[1] Together with chelation therapy, abatement of lead-based paint hazards by traditional practices in homes of children with symptomatic lead poisoning contributed to the drastic reduction in the numbers of reported lead-related deaths and recurrences of acute encephalopathy in Baltimore by the late 1960s.[2,3]

More recently, clinical and epidemiological studies have revealed that body burdens of lead previously considered safe are associated with significant long-term adverse health effects which can occur even in the absence of clinical symptoms.[4–7] Since the 1960s, the PbB considered unacceptable has been progressively lowered from 2.90 μmol/L to the current level of 1.21 μmol/L (25 μg/dl).[8–11] New concerns are being raised about the risk of adverse neurodevelopmental effects as PbBs increase above the 0.48–0.72 μmol/L range.[12–15] Lead-contaminated house dust (PbD) ingested via repetitive hand-to-mouth activity is now recognized as a major contributor to the total body lead burden of children.[16–18]

Studies in the 1980s suggest that traditional abatement practices are inadequate for reducing exposure so that children's PbBs can be maintained within acceptable levels. Chisolm, *et al*,[19] found a recurrence rate of 47 percent of PbBs greater than 2.36 μmol/L in children following chelation therapy and reoccupancy of older dwellings abated by traditional methods. Charney, *et al*,[20] showed that repeated dust removal following lead-paint abatement was associated with a modest reduction in children's PbB whereas lead-paint abatement alone was not. Various case reports indicate that abatement and refinishing activity in homes with lead-based paint can result in increased PbBs in workers and children.[21–25]

Despite changes in our understanding of the epidemiology of childhood lead toxicity and recognition of low-level adverse health effects, practices for abating residential lead-based paint have remained essentially unchanged for the last 40 years. Only recently have a small number of states established upgraded abatement requirements (Maryland, Massachusetts, Minnesota).[26–28] This paper reports on an observational prospective study in which traditional abatement practices were evaluated and compared with modified practices intended to address some of the deficiencies of traditional practices. The study was a natural experiment in which the investigators had no control over the implementation of either form of abatement.

Methods

Study Design

Serial measurements of lead in interior surface dust (PbD, mg/m^2) and children's blood were made pre-abatement, post-abatement, and six months post-abatement. A subset of dwellings abated by traditional methods had additional PbD measurements at one and three months post-abatement. Households were identified through the Baltimore City Health Department, which inspected the dwellings of children identified with lead toxicity and enforced abatement requirements. During the enrollment period (March 1984 to January 1985), property owners either performed required lead-paint abatement themselves using traditional practices or elected to have city crews perform the abatement using modified traditional practices. City abatements were being offered for the first time and were done according to principles similar to those subsequently outlined by the Centers for Disease Control (CDC).[11]

Appendix A describes and compares the two abatement practices. Unlike traditional practices, modified practices included more than minimal efforts to clean the dwelling following abatement, dispose of debris off-site, and to protect workers, occupants and their belongings. Unlike traditional practices, modified practices excluded the use of open-flame burning and sanding techniques and included the repainting of abated surfaces.

Local abatement requirements consisted of addressing deteriorated paint on surfaces up to four feet from the floor

and all paint on easily accessible "biting" surfaces where the lead content of the paint was > 0.7 mg/cm^2 by x-ray fluorescence or 0.5 percent by weight by wet chemical analysis. At the time of enrollment, toxicity was defined by the CDC as a.PbB > 1.40 μmol/L (> 29 μg/dl) of whole blood together with a free erythrocyte protoporphyrin > 49 μg/dl of whole blood.[10] This study was approved by the Committee on Human Volunteers at the Johns Hopkins School of Hygiene and Public Health.

Study Sample

Seventy-one (71) study dwellings (53 traditional abatement, 18 modified abatement) had PbD measurements from pre-abatement and at least one point in time post-abatement. Attrition during the six months post-abatement was the same in both groups (17 percent).

Most study dwellings were pre-1940 row homes occupied by low-income tenants. Prior to abatement, all dwellings had multiple interior surfaces coated with lead-based paint and at least one child with PbB > 1.40 μmol/L. Based on walk-through inspections of 66 of the 71 study dwellings at the end of the study, dwellings were rated as follows using a classification system designed by housing professionals for use in this study: fairly well maintained (traditional = 8, modified = 6); substandard (poorly maintained yet maintainable: traditional = 30, modified = 10); and grossly substandard (not maintained and in need of renovation: traditional = 12 modified = 0).

Children in the 71 study dwellings abated by traditional or modified practices from which dust data were obtained, and children in an additional 25 dwellings abated by modified methods for which there were no dust-lead measurements, were included in the analysis of PbB change if they met the following criteria: age: 9 to 72 months; not known to be mentally retarded; spent 75 percent of his/her time living in the abated dwelling; resided in the abated dwelling pre- and post-abatement and had PbB determinations on venous blood at pre-abatement and at least one time post-abatement. Due to the confounding influence of chelation therapy on PbB and body burden of lead, children with histories of therapy at the time of enrollment were excluded from PbB analyses (except for the analysis of the association between PbB and PbD). PbB data were obtained by medical record review of children in the 25 dwellings abated by modified practices for which there were no dust-lead measurements.

Data Collection and Laboratory Methods

Over 3,100 dust samples were collected for lead analysis from nearly 900 sites in 71 study dwellings. From 12 to 24 dust samples were collected from the same floor, window sill, and window well (portion of window that receives the sash when window is closed) surfaces at each home visit. Samples were collected from most rooms, with particular attention to areas where children spent most of their time as reported by parents. As in previous studies[20,29,30] sample collection and preparation was done by the method of Vostal, *et al*,[31] except that no attempt was made to avoid collecting loose chips of paint and samples were analyzed using flame atomic absorption spectrophotometry at the Kennedy Institute's Trace Metals Laboratory. PbD results were expressed as mg Pb/m^2. The methods of this study underestimate the total amount of lead per surface sampled, particularly on window wells where the largest quantities of visible particulate matter and loose chips of paint were collected and the highest PbD levels were measured (see Appendix B).

Venous blood specimens were collected in low-lead vacuum tubes by the subjects' usual health care providers. Specimens were analyzed by atomic absorption spectrophotometry[32] by the Maryland Department of Health and Mental Hygiene or by anodic stripping voltammetry[33] at the Kennedy Institute's Trace Metals Laboratory using the rapid blood lead analyzer (Environmental Sciences Associates, Inc. Model 3010A, Bedford, MA). Inter-laboratory variation was minimal (data available from authors). Both laboratories served as reference laboratories for the CDC's blood lead proficiency testing program. After considering the precision of the analytical method using anodic stripping voltammetry (1 SD = 0.08 μmol/L, and modified Delves cup (1 SD = 0.16 μmol/L)[34], a change in PbB was defined as an increase or decrease of 0.24 μmol/L (5 μg/dl) or more (i.e. a change of which exceeds 1.5 to 3 standard deviations).

Data Analysis

In the absence of a federal standard for lead in interior surface dust, a target PbD of < 1.5 mg/m^2 was set for evaluation purposes. This target was based on an earlier study which reported all but one PbD level in modern suburban homes under 1.18 mg/m^2 (mean 0.29 mg/m^2).[30] Using a different method of sample collection and analysis, similar levels were reported (0.04 to 1.23 mg/m^2, GM = .20 mg/m^2) in public housing units where children were found to have acceptable PbBs (mean = 0.48 μmol/L).[35]

PbD values were found to be log-normally distributed. Units of analysis were individual PbB values and PbD values transformed using natural logarithms. PbB distributions were not log-normalized due to the restricted range of values. Multiple regression models based on maximum likelihood estimates were fit to PbB and to PbD at various points in time. Important covariates were included in the models. Since PbD values within dwellings were correlated (first order correlation coefficient for pre-PbD data ordered by household and surface type was 0.39), a correction for correlated residuals was made by adjusting the standard errors of the beta coefficients using an in-house program and retesting the significance of the variables.

Results

Dust-Lead Findings

Pre-Abatement Dust-Lead: Pre-abatement PbD levels ranged from less than 0.27 mg/m^2 to: 272 mg/m^2 on floors, 1076 mg/m^2 on window sills, and 4059 mg/m^2 on window wells. Dwellings abated by traditional and modified practices had comparable PbD before abatement (Table 1) despite differences in housing condition. Surface type and season were significant predictors of pre-PbD levels. Knowledge of which surfaces were identified for abatement was not a predictor of pre-PbD (see Table 2).

Pre-Post Change in Dust-Lead: Increased PbD levels were measured immediately following traditional abatement (usually within 48 hours) on abated window sills and on floors in close proximity to abated surfaces (Table 1). Increases at individual sites were typically 10 to 100-fold over pre-abatement levels. Most window sills (31/39) abated by the modified practices had lower PbD levels compared to pre-PbD levels. However, most window sill and floor surfaces remained outside the target range (<1.5 mg/m^2) even after final clean-up. Window wells, which were not treated during abatement by either group, had post-PbD levels which remained high in both groups (Table 1). Immediate post-abatement PbD levels in dwellings abated by modified prac-

[c] Pre-PbD distribution was centered around its geometric mean.

tices were significantly lower than post-abatement levels in dwellings abated by traditional methods after adjusting for Pre-PbD and covariates (Table 2).

Data from a subset of 19 dwellings with traditional abatement and more frequent PbD monitoring showed downward trends in PbD on floors and window sills which were greatest during the first month. Window well PbD levels remained high. By three months, PbD levels at floors, window sills, and window wells were similar to levels observed in these homes at six months and in all study homes at six months (Table 1).

Six Month Dust-Lead: At six months, PbD levels were similar to, or greater than, their respective pre-abatement levels in both abatement groups (Table 1). Also, at six months, PbD tended to increase as housing condition worsened.

Blood-Lead Findings

Of 151 children eligible for PbB analysis, 78 (52 percent) (n = 46 traditional abatement; n = 32 modified abatement) were included in at least one component of the PbB analysis. The other 73 children did not have PbB determinations on venous blood at pre-abatement and at least one point in time post-abatement due to inadequate follow-up by their health care providers. No evidence was found for differences in PbB follow-up by abatement group, sex, age, race, season, housing condition, history of chelation, or location of child during abatement. Insufficient data precluded a comparison of pre-PbB levels by follow-up status.

Pre-Abatement Blood-Lead: Children from dwellings abated by traditional and modified practices had comparable pre-abatement PbBs (see Table 3) and comparable ages at abatement (traditional: 34.6 months, modified: 34.0 months). No differences were found in Pre-PbB by sex or by housing condition.

Post-Abatement Blood-Lead: Within one month of abatement, children in traditionally abated dwellings had significantly higher PbBs than children living in dwellings abated by modified practices (see Table 3). Individual increases in PbB were observed across a range of pre-PbB values from 1.16 to 2.51 μmol/L) (24 to 52 μg/dl). Overall, 13/27 (48 percent) of children in dwellings abated by traditional practices had PbB increases (defined as 0.24 μmol/L or more). Of these, nine were hospitalized for the first time for chelation therapy (PbB > 2.36 μmol/L). Of 19 children in dwellings abated by modified practices, three (16 percent) had PbB increases, two of whom were hospitalized for the first time for chelation therapy. Children with reported home contact during abatement had significantly higher post-PbB

TABLE 3—Pre- to Post-Abatement Change in Blood Lead Concentration for Children Never Chelated Pre-Abatement

Modified Abatement (n = 19)	1.66	(.10)	1.71	(.12)	+0.05 (−0.09, 0.19)

[a] Post-abatement – within 1 month

than children with no reported contact (mean difference +0.35 μmol/L). In regression analysis (n = 46 children, R^2 = .65), abatement group was a significant predictor of post-abatement PbB after controlling for pre-PbB, season and whether or not the child had contact with the home during abatement.

Six Month Blood-Lead: At six months, children (traditional = 14, modified = 15) with no history of chelation therapy (PbB < 2.36 μmol/L) continued to have elevated PbBs (mean = 1.48 μmol/L) which were not significantly different from their pre-abatement PbBs (mean = 1.57 μmol/L). By six months post-abatement, five other children (three traditional abatement, two modified abatement) had experienced PbB > 2.36 μmol/L and had received chelation therapy.

Correlation between PbD and PbB: At pre, post, and six months post-abatement, children's PbBs were significantly correlated with floor and window sill PbD in their homes (Table 4).

Discussion

High levels of lead in dust were measured in homes of children with PbB > 1.4 μmol/L. Before and after abatement of lead-paint, 71 study dwellings had geometric mean PbD on floors, window sills, and window wells that were approximately 10 to 600 times greater than the PbDs reported by others in modern suburban homes and in public housing units where children had acceptable PbBs.[30,35] Study homes in the most deteriorated condition tended to have the highest PbD levels over time and the highest risk of chelation therapy (PbB > 2.36 μmol/L) among occupant children. These homes had multiple problems such as roof and plumbing leaks, holes in walls, deteriorated floors, and defective heating systems.

Most components of windows were not abated of lead-paint, and window wells remained reservoirs of very high levels of PbD during the entire study period regardless of housing condition. Most windows in study homes were deteriorated and within easy reach of young children. We observed that repeated opening and closing of old windows resulted in further deterioration of lead-painted surfaces on interior and exterior window components and contributed to the accumulation of visible dust and chips of paint on window wells. Higher interior PbD levels observed during spring and summer may be related, in part, to more frequent opening and closing of windows by occupants during these seasons. Others have also reported differences in PbD levels by season, housing characteristics, and location within rooms.[29,36,37] Soil lead was not measured in this study, although others have reported significant correlations between concentrations of lead in surface soil and interior house dust.[16,37]

Despite the implementation of improved practices, modified abatements, like traditional abatements, did not result in any long-term reductions of levels of lead in house dust or the blood of children with pre-abatement PbBs between 1.16 and 2.51 μmol/L. Traditional abatement practices also resulted in acute increases in PbD and the PbBs of children. Some received chelation therapy (PbB > 2.36 μmol/L) for the first time following abatement. With alternative abatement practices children were less likely to experience acute increases in PbB. However, post-abatement PbD levels overall exceeded the target range (<1.5 mg/m^2) despite improvements in PbD levels at most abated sites. Household respondents reported that one-third of children in both abatement groups had some contact with the home during abatement (day, night, or both) against the advice of the city health department. Home contact was associated with significant increases in children's PbB in this and other reports.[24,25] As in previous studies, a significant relationship was found between PbB and dust-lead levels.[36–38]

Inskip and Atterbury have reported high rates of deposition of lead on surfaces in close proximity to surfaces abated by methods used in this study as follows: heat gun and torches: 1 to 5 mg Pb/m^2/hour, sanding: 50 to 200 mg Pb/m^2/hour.** One dwelling in this study abated by open-flame burning and sanding was noteworthy because two study children and a third who moved into the dwelling after abatement had a total of five admissions for chelation therapy (PbB > 2.36 μmol/L) during the entire post-abatement study period.

In addition to the use of high dust-generating methods, poor containment, clean-up, and disposal practices associated with traditional abatements (Appendix A) exacerbated the problem of exposure to lead-bearing dust on household surfaces. Exposure to lead-bearing dust is particularly hazardous for children because hand-to-mouth activity is recognized as a major route of entry of lead into the body and because absorption of lead is inversely related to particle size.[39] Another study[40] showed that 21 percent of lead in house dust was found in particles of size less than 44 microns. This suggests that standard vacuums used by city crews in performing modified abatements may not have been adequate to trap lead-bearing particulates which may have been

**Inskip M, Atterbury N: The legacy of lead-based paint: potential hazards to "do-it-yourself" enthusiasts and children. Proceedings of the International Conference on Heavy Metals in the Environment, Heidelberg, West Germany, 1983. CEP Consultants, Ltd., Edinburgh, UK, pp. 286–289.

TABLE 4—Pearson Correlation (r) Over Time: Children's Blood Lead Concentrations and Geometric Mean Dust-Lead Levels in Their Homes

	Floor PbD			Window Sill PbD		
Blood Lead	r	95% CI	n	r	95% CI	n
Pre-Abatement[a]	0.35	(.08, .57)	50	0.31	(.04, .54)	50
Post-Abatement[b]	0.48	(.20, .70)	37	0.40	(.07, .66)	33
6 Months Post-Abatement[c]	0.54	(.23, .76)	30	0.53	(.18, .75)	27

[a] Includes children chelated pre-abatement (admission PbB value used) and children with no history of chelation therapy pre-abatement.

[b] Includes children chelated and discharged to abated dwellings who had re-exposure defined as PbB rebound followed by an increase in PbB to or above prior admission level with subsequent readmission (readmission PbB used for six children in floor PbD:PbB correlation and for four children in window sill PbD:PbB correlation).

[c] Includes children with no history of chelation and children six months post-chelation.

exhausted, re-entrained into the air, and redeposited.

PbD levels and the ability to reduce them appear to be related to the condition of household surfaces. Within and across study dwellings, smooth floor surfaces (e.g., vinyl tile, linoleum) tended to have lower PbD levels than wooden floors, which in our study sample were usually pitted, splintered, and worn. A relationship between surface condition and effectiveness of clean-up was found in subsequent studies which covered or coated old floors prior to final clean-up.***

The lack of long-term effectiveness for reducing lead exposure may have been due to the reliance upon abatement of certain surfaces up to four feet from the floor that children could easily reach, mouth, and chew. In this respect both the traditional and modified abatement practices reflected an outdated understanding of the etiology of childhood lead poisoning. These limited forms of abatement did not address high sources of lead-contaminated dust such as windows and left the potential for ongoing exposure to lead in paint and dust. Poorly maintained housing was observed to deteriorate further after abatement. Poor containment and clean-up practices during abatement may also have contributed to increased and ongoing exposures to lead-bearing dust on upholstered furnishings and in air ducts and vents.

Lead in paint, dust, and soil now constitute the major sources and pathways of lead exposure for US children. Recent estimates are that 42 million US dwellings contain lead-based paint, and 1.8 million US children live in deteriorated homes with lead-paint.[18] The public health goal vis-a-vis lead toxicity in children is to maintain PbBs of children and fetuses below levels associated with adverse health effects (i.e. PbB below 0.48–0.72 μmol/L).

There is a need for a new approach[41] to abating residential lead-based paint which would include: 1) more extensive, if not complete, abatement of lead-paint on interior and exterior surfaces using replacement, paint removal and encapsulation methods which prove to be safe, practical and effective in the long-term; 2) the reduction of lead-bearing house dust by the application of the following: (a) more effective clean-up measures which may well require the use of vacuums equipped with high efficiency particle air (HEPA) filters, (b) proper disposal of abatement waste, (c) the use of engineering and work practice controls to minimize and contain lead-dust produced during abatement, and (d) upgraded work practices to protect workers, occupants, their belongings, and the environment; 3) post-abatement clearance testing of lead in interior surface dust prior to reoccupancy; and 4) evaluation of costs and health and environmental outcomes of alternative abatement methodologies. The findings of this study have provided the basis for studies now in progress based upon the principles just cited. This new approach also provides for temporary relocation of families and their belongings to safe housing during abatement; worker education, training and certification; and takes into account the overall condition of dwellings, the conditions of specific painted surfaces and substrates, and other needed repairs as adopted in part in recent state regulations.[26,27] Post-abatement clearance testing for interior dust-lead prior to reoccupancy has been introduced recently in Maryland and Massachusetts using interim state standards.[26,27]

***Unpublished data, Baltimore City Health Department, Kennedy Institute

The role of lead-dust and hand-to-mouth activity in childhood lead poisoning was first recognized by Gibson in 1904.[42] In applying this knowledge to a new approach to abatement, we would do well to consider the following which Benjamin Franklin wrote in a letter to Benjamin Vaughan in 1786:

> "You will see by it that the Opinion of this mischievous Effect from Lead, is at least above Sixty Years old; and you will observe with Concern how long a useful Truth may be known, and exist, before it is generally receiv'd and practic'd on."

ACKNOWLEDGMENTS

This work was supported by the Baltimore City Health Department, the National Center for Health Services Research (grant no. HS 05053), and by a Biomedical Research Support Grant (grant no. 2S07-RR05445-27). Findings were presented in part at the 6th International Conference on Heavy Metals in the Environment, New Orleans, LA, September 1987.

We are indebted to Evan Charney for his guidance and support and to the late Rupla Eshai and Susan Guarnieri and the Baltimore City Health Department for their cooperation and to Alan Goldberg, Susan Baker and Barbara Starfield for their valuable critical review of this manuscript.

APPENDIX A

Comparison of Traditional and Modified Abatement Practices

	Traditional Abatement	Modified Abatement
Extent of abatement	Up to 4 feet from floor	Up to 4 feet from floor[a]
Methods	Torch and/or sander	Heat gun
Repainting	No	Yes
Clean-up	Minimal[b]	Thorough[c]
Disposal of debris	Haphazard[d]	Off-site
Worker protection	Minimal[e]	Adequate[f]
Occupant Protection	Minimal	Some[g]
Protection of belongings	Minimal	Some[h]
Supervision of workers	No	Yes[i]

[a] Interior side trim of windows was also abated above four feet from floor.
[b] Typically dry sweeping, if done at all.
[c] Wet cleaning with high-phosphate detergent together with dry vacuuming using standard shop vacuums.
[d] Abatement debris was often left uncontained inside or outside of the home.
[e] No or inadequate respiratory protection; no blood-lead monitoring; often no protective clothing and gear.
[f] Workers were trained in use of respirators, fit tested, and provided with half mask air purifying respirators with high efficiency particle air (HEPA) filters. Overalls were provided and laundered regularly; blood lead monitoring was done.
[g] City crews had better clean up practices, and were more likely to warn parents of hazards and provide instructions on dust control. However, children in both abatement groups had some contact with the home during abatement.
[h] Furnishings and some floors were covered with tarps and kitchen items and clothes were stored in sealed closets and cabinets.
[i] City crews were supervised on-site during abatement.

APPENDIX B

Efficiency of Collection and Analysis of Lead in House Dust

Sampling was done on abated and non-abated surfaces by wiping with alcohol impregnated towelettes (14.6 cm × 20.3 cm). Dust was collected from 0.09 m^2 (one square foot) of floor surfaces using a template. Window sills and window wells were measured and alternate halves were sampled at each visit. Surfaces were wiped back and forth twice in each direction and the procedure was repeated after folding the towelette in half.

Sampling efficiency was assessed by rewiping the same surfaces up to 10 times. Sampling efficiency of a single towelette appeared to be positively related to the degree of smoothness of the surface and inversely related to the loading (total mass) on a surface. When the PbD level was less than 1.0 mg/m^2 on an initial wipe from smooth surfaces with no visible chips of paint, then non-detectable levels (<0.5 ppm lead in 20 ml extractant), or levels just above them, were usually found on the second or third towelette. When the PbD level was greater than 100 mg/m^2 on an initial wipe, and when chips and/or particulates were visible, then PbD levels greater than 10 mg/m^2 were usually detected through at least the tenth towelette.

Efficiency of elution was inversely related to the ratio of mass of sample to mass of extractant (s/e ratio). Elution efficiency at the Trace Metals Laboratory was as follows for the following standard reference materials (SRM) of the National Bureau of Standards: Urban particulate SRM #1648 (0.655 percent lead by weight): 69 to 100 percent as s/e ratio ranged from 1:67 to 1:6667; Paint SRM #1570 (11.87 percent lead by weight): 24 to 93 percent as s/e ratio ranged from 1:76 to 1:208; Orchard leaves (use due to high silica content) SRM #1571 (45 μg Pb/g): 32 to 58 percent as s/e ratio ranged from 1:14 to 1:21.

Placing Patients in the Queue for Coronary Revascularization: Evidence for Practice Variations from an Expert Panel Process

C. David Naylor, MD, DPhil, Antoni Basinski, MD, PhD, Ronald S. Baigrie, MD, Bernard S. Goldman, MD, and Jonathan Lomas, MA

Abstract: A panel of 16 cardiologists and cardiac surgeons rated 438 case scenarios for the maximum acceptable delay prior to revascularization, using a scale with seven interventional time frames and two nodes for designating dubious or inappropriate cases. If consensus was defined as agreement by 12 or more panelists, only 1.4 percent of the case scenarios showed consensus on a single rating. Dividing the scale into three broad clinical categories (revascularize promptly, place on a waiting list, or no intervention), 11.4 percent of scenarios showed all 16 panelists agreeing on a single category, rising to 59.4 percent of scenarios if agreement by 12 panelists was accepted as a consensus. The mean difference between the panelists' highest and lowest urgency ratings yielded waiting time differences of two weeks for scenarios of very unstable angina, and more than three months for those with stable angina. However, in a regression model, individual panelist factors on average had less effect than clinical features such as severity and stability of angina, or stenosis of major coronary arteries. These findings strongly support the need for consensus criteria to ensure that triage practices are consistent and fair, and also suggest that widespread adoption of a standardized approach to revascularization priorities may be feasible (*Am J Public Health* 1990; 80:1246–1252.)

Introduction

In many countries, limits on medical facilities and manpower make it difficult to offer rapid coronary revascularization procedures to all patients with coronary heart disease who might benefit. Cardiac surgeons and cardiologists currently assess patients according to various informal criteria in an attempt to ensure that persons with more symptoms or a higher time-dependent risk of ischemic events are revascularized expeditiously—a sorting process generally termed triage. However, no formal schema for revascularization triage has been accepted or even proposed in such a fashion as to generate widespread debate.

In the Canadian province of Ontario, waiting lists for elective coronary artery bypass surgery [CABS] during 1988 ranged between two and twelve months in five of nine hospitals with open heart surgery facilities, and the three cardiac surgery centers in Toronto had a combined waiting list of 848 patients as of January 1989.[1] These waiting times have created an ethical imperative to ensure that patients with symptomatic coronary disease at least receive attention according to perceived urgency of clinical need. Providers and the provincial government therefore agreed that formal triage criteria should be developed and applied in a pilot project for Toronto-area hospitals. To arrive at a consensus about guiding clinical principles in this area of practice, an expert panel of cardiologists and cardiac surgeons was convened. We postulated that the lack of accepted criteria for triage might be associated with considerable interpractitioner variation in whether—and where—patients were placed in the waiting lists for coronary revascularization. The formal group process followed by the panelists generated evidence about the nature and extent of inter-practitioner agreement and disagreement. We herein present this evidence and discuss its implications for promotion of a uniform approach to triage practices.

Methods

Panel Process

The group process followed by the revascularization panel was a variant on techniques used by researchers at the RAND Corporation[2–4] and the Canadian National Consensus Conference on Aspects of Cesarean Birth.[5,6] The 16-man panel included five cardiovascular surgeons from academic centers; six cardiologists practicing in academic centers, three of whom had extensive experience with percutaneous transluminal coronary angioplasty [PTCA]; and five cardiologists practicing in community hospitals that refer patients to the Toronto academic centers offering CABS or PTCA (Appendix A). Drawing on pre-circulated background materials, the panelists met for a day in October 1988 and agreed on factors that would be most important in determining urgency of need for revascularization; levels within each factor were also set out (Appendix B). An urgency rating scale was adopted, with several time-frames for revascularization and two appropriateness ratings for indicating those instances where triage to revascularization seemed questionable or contraindicated (Appendix C).

After the first panel meeting, an Urgency Rating Questionnaire was compiled, permuting the factors agreed upon by the panelists into patient case scenarios. Implausible scenarios were eliminated, and levels of given factors deemed unlikely to affect decision-making were eliminated or combined, leaving 438 separate case scenarios (sample materials available on request). Case scenarios were oriented primarily to urgency ratings, in that all patients had at least significant single vessel disease and all were presumed to have clinically unequivocal angina. The questionnaire was organized into five chapters according to the level of what was *a priori* believed to be the most important factor—the pain syndrome, defined as the severity or stability of anginal symptoms, and

response of those symptoms to medical therapy (Appendix B).

The panel had agreed that a single set of criteria would be developed for revascularization in general, pending the later generation of a separate set of triage criteria for PTCA. Panelists were therefore to rank scenarios with a view to employing either PTCA or CABS, depending on the clinical features. The majority of scenarios, however, were anatomically appropriate for CABS rather than PTCA (Appendix B). Panelists were instructed that the waiting period should be that deemed reasonable given: the presumed risk of death from ischemic events due to delayed revascularization, as suggested by clinical experience and evidence from a precirculated literature review; the presumed ongoing morbidity as a result of anginal symptoms; and other relevant factors as determined by the individual panelist. They were specifically enjoined to approach the questionnaire with an understanding that resources for coronary revascularization were in competition with other worthy programs. The waiting period was presumed to start from the time that anatomical data from angiography were available in the presence of appropriate symptoms of angina.

To help ensure a shared body of knowledge, a literature review was compiled to accompany the Urgency Rating Questionnaire. This review focused on any known temporal differences in risk of death from ischemic events for patients receiving medical rather than surgical therapy, and was organized according to each of the agreed-upon factors, singly and/or in combination with other factors. Panelists were urged to read the document prior to completing the questionnaire, and were also supplied with an executive summary of it for ease of reference.

Our process differed from that developed by the RAND researchers in two key respects. The Ontario triage panelists met initially to agree on the scale and the factors to be incorporated into the Urgency Rating Questionnaire, completed the questionnaire, received by mail their individual ratings as compared to all other panelists, and finally met again to arrive at consensus criteria for triage practices. This process actually reduced one potential source of interpractitioner disagreement—rejection of the plausibility of either the factors used to construct the case scenarios, or the combinations of factors into particular case scenarios. In contrast, Park, *et al*, report that indications lists were substantially revised by the RAND panelists when they met to review their appropriateness ratings for various case scenarios.[2] The other difference in process was re-rating of scenarios. The RAND panelists rated their scenarios twice: first independently, and again at a panel meeting, taking into account their results as compared to other panelists. The Ontario panelists rated scenarios once, without knowledge of their peers' ratings.

Statistical Analysis

With 16 panelists rating 438 case scenarios, there were only eight missing ratings out of a possible 7,008; appropriate allowance was made for them in all analysis. Descriptive measures of agreement and disagreement are explained with the relevant results. More formal statistical analysis involved two methods: an index of agreement for multiple raters and intraclass correlation coefficients.

The agreement index (Appendix D) was constructed to estimate the probability that two randomly chosen panelists, drawn without replacement, would agree on the classification of a randomly chosen scenario. This index—termed P_a—was calculated for the entire set of scenarios, and for each level of angina symptomatology, hereafter termed, "pain syndrome." Agreement was calculated both for exact scale ratings and within three sets of scale ratings (raings 1–4, 5–7, and 8–9) representing similar clinical decisions. The agreement ratings are reported both as overall levels of agreement and corrected for chance agreement between panelists, i.e., a kappa correction.[7] This correction reduces the agreement probability by accounting for the overall likelihood of any two raters agreeing by chance, given the overall pattern of responses across the entire set of 438 scenarios.

The indices of agreement do not penalize panelists for greater scale disagreement. That is, be it with respect to exact agreement or agreement by approximate clinical approach, two randomly drawn raters scoring a scenario for intervention within 24 hours ("extremely urgent") versus intervention within 3–6 months ("marked delay") are both recorded simply as disagreeing, but the extent of this discrepancy is not captured. To reflect the ordinal nature of the rating scale, intraclass correlation coefficients [ICCs] were calculated.[8] Analogous to weighted kappa statistics, the ICCs show the expected numerical correlation between the ratings of two randomly chosen panelists rating the same randomly chosen scenario. For ease of analysis, we assume that the two non-interventional ratings ("questionable" and "inappropriate") follow after the final time-node, "marked delay." This simplifying assumption tends to increase the correlation between panelists' ratings in case scenarios with scores reflecting low urgency, and reduces correlation in scenarios with high urgency. However, differences between "inappropriate" and "marked delay" are arguably much less important than between the former and "extremely urgent."

Linear regression analysis[9] was also performed to estimate the relative impact of practitioner versus clinical factors. To facilitate analysis, the entire scale was again treated as ordered (see above for justification).

Results

Descriptive Grouping of Ratings

For each scenario, one may either consider the number or proportion of panelists agreeing on a given set of contiguous rating categories (scale agreement) or the number of contiguous ratings required to encompass the ratings of a given number of panelists (panel agreement). Thus, consensus consists of panel or scale agreement, or both. Complete agreement on a single rating by all panelists never occurred. If the definition of panel agreement was relaxed to include as few as 12/16 panelists, i.e., agreement by at least 75 percent of the panel, then only 6/438 (1.4 percent) of the case scenarios showed consensus on a single rating. With a further relaxation of the definition of panel agreement, to a simple majority or ≥ nine panelists, agreement on a single rating rose to 102/438 scenarios (23.2 percent). Relaxed definitions of scale agreement were also applied, with the entire nine-point scale taken as contiguous. To encompass the responses of all panelists 50 percent of the time, it was necessary to relax the definition of scale agreement to five contiguous points. On the other hand, by allowing some latitude in definitions of both scale and panel agreement, frequent clustering of responses was evident. For example, at least three-fourths of panelists agreed within a three-point range in over 80 percent of cases.

Indices of Exact Scale Agreement

The probabilities that any two randomly drawn panelists would agree on a particular rating for a given scenario are

shown in Table 1 according to each pain syndrome and overall. The exact agreement is consistently at the 25–30 percent level, falling somewhat only for the highest urgency scenarios—unstable angina with persisting symptomatology requiring parenteral therapy for control. The degree of agreement corrected for chance is poor.

Because our primary concern was with urgency rather than appropriateness, these indices were recalculated including only the time-related ratings between "emergency" (node 1) and "marked delay" (node 7), i.e., eliminating appropriateness as a source of disagreement. The resulting agreement on urgency ratings ran 30–40 percent, and was only moderately higher than in the total scale case (data available on request to author).

Indices of Approximate Scale Agreement

Clinical divisions: The first four ratings on the scale (Appendix A) imply that patients will be revascularized on the same admission if hospitalized for medical therapy or catheterization, or readmitted within two weeks; whereas the next three ratings will be on outpatient waiting lists. We term these two categories respectively "DO" and "WAIT", and the last two non-interventional ratings, "NOT".

Only 11.4 percent of scenarios showed all 16 panelists agreeing within one of these three clinically pertinent categories. However, if panel agreement was re-defined as congruence among ≥12 clinicians, categorical agreement was found for 59.4 percent of scenarios. Moreover, as shown in Table 1, the overall P_a increased greatly, rising to about 65 percent. Thus, there was evidence of a general agreement on a general approach to these patients. The probabilities of agreement between two randomly drawn panelists were even higher (82 percent) when appropriateness ratings were eliminated, leaving only the clinical dichotomy of "DO" versus "WAIT" (data on request to author).

When divided by pain syndrome, the indices reveal a significantly higher degree of agreement for the most unstable patients—the opposite of the trend when exact agreement was sought (Table 1). This enhanced agreement for an overall approach was attributable to the fact that patients still on parenteral therapy obviously could not be discharged from hospital, would almost invariably fall into the "DO" category, and only occasionally be rated as "WAIT". The lower index for the exact ratings was due to poor agreement among panelists within the first four ratings; only four panelists rated any scenarios at node 1 ("emergency").

It should be noted that there was considerable difference among panelists in frequency of use of "NOT" ratings—"questionable" or "inappropriate". While 10 panelists rated between 49 and 105 scenarios in "NOT" categories, the extent of disagreement about appropriateness is suggested by the fact that the other six applied "NOT" ratings to 1, 20, 37, 135, 172, and 200 scenarios respectively. One way of examining divisions of opinion about appropriateness is to consider the proportions of scenarios where ≥4 panelists rate "DO" and ≥4 rate "NOT". Broken down by pain syndrome, the percentages of scenarios with this pattern of disagreement were as follows: mild to moderate stable angina, 4.5 percent; severe stable angina, 1.6 percent; unstable angina with adequate restabilization on oral medical therapy, 4.4 percent; unstable angina with incomplete stabilization on oral medical therapy, 24.2 percent; and unstable angina requiring ongoing parenteral medication, 16.7 percent. Note that the latter two sections of the Urgency Rating Questionnaire were actually identical apart from the pain syndrome. The reduced frequency of "NOT" versus "DO" disagreement was accordingly due entirely to the fact that patients requiring parenteral therapy were believed so ill that the risk-benefit ratio of revascularization was deemed more uniformly acceptable, leading to greater consistency in application of "DO" ratings.

Numerical Scale Association: Intraclass correlation coefficients are also displayed in Table 1. When separated by the five levels of pain syndrome, the intraclass correlations sharply decrease with more severe or unstable angina. This is similar to the situation for exact scale agreement using the non-ordinal index of agreement, and is due to clustering of ratings (e.g. 88 percent of panelists' ratings are between time-nodes 1 and 4 for the most severe pain syndrome). Hence, while there is relatively low variability between scenarios, there is also little overall agreement on the exact timing of revascularization. As well, any disagreement about appropriateness further reduces the correlation coefficient, because of numerical distances between scale points under an assumption of ordinality (e.g., time-nodes 1-4 versus non-intervention nodes 8-9).

Agreement and Disagreement by Individuals and Subgroups

There were no significant differences in total absolute distance from the median scenario ratings or frequency of

TABLE 1—Agreement on Urgency/Appropriateness Rating

	Stable Angina Symptoms on Medical Therapy		Unstable Angina Symptoms on Medical Therapy			
	Mild-moderate	Severe	Resolved	Partly Resolved	Persisting	Overall
Exact						
P_a*	0.30	0.31	0.29	0.30	0.25	0.29
SE (P_a)	0.01	0.01	0.01	0.01	0.01	0.01
Kappa	0.18	0.19	0.17	0.18	0.12	0.16
Clinical Category#						
P_a	0.58	0.65	0.56	0.56	0.81	0.65
SE (P_a)	0.02	0.02	0.02	0.01	0.01	0.01
Kappa	0.33	0.44	0.30	0.29	0.70	0.43
Scale Correlation ICC+ (random effects)	0.49	0.51	0.40	0.16	0.13	0.51

*P_a = probability of agreement for two randomly drawn raters on a randomly chosen scenario; the kappa correction is unweighted. #Scale collapsed into three clinical categories, "DO" within two weeks (time-nodes 1–4); "WAIT" up to six months (time-nodes 5–7); and "NOT" triaged (ratings 8 for "questionable" or 9 for "inappropriate"). +ICC = intraclass correlation coefficient, analogous to a weighted kappa.

outlier status (defined as being greater than one scale point from the median rating) according to practitioner experience, academic or non-academic center for practice, and surgical versus cardiological orientation.

The Practitioner Factor in Context

We used regression techniques to determine, within each pain syndrome and for each practitioner, the influence of practitioner variability as opposed to that stemming from the clinical factors incorporated into the questionnaire. Results for the three panelists with largest and smallest absolute coefficients are shown in Table 2, showing respectively systematic departure from, and congruence with, the mean ratings of the group for any given scenario.

Table 3 presents the regression coefficients for various clinical factors, as well as the median absolute value of the panelist coefficient for each pain syndrome. As suggested by the change *across* chapters due to the pain syndrome alone, this was the dominant determinant of ratings. The influence of the panelists is suggested by comparing the magnitude of the regression coefficients for clinical factors *within* any given pain syndrome to the regression coefficients for the median panelist. The latter is significantly smaller than key clinical variables such as pain syndrome or stenosis of major coronary arteries (standard errors are approximately 0.10 for all coefficients, including the panelist factor.) However, as indicated in Table 2, some panelists did systematically differ from the mean panel rating to a much greater extent.

Urgency Rating Discrepancies in Isolation

Beyond the indices of agreement on urgency ratings calculated above, we sought also to quantify the extent of discrepancies among panelists rating a given scenario between 1 and 7. Two measures were calculated: the maximum discrepancy of ratings within each scenario, and the discrepancy between the extreme ratings when the highest and lowest 25 percent of ratings were eliminated for each scenario. (The number of ratings deleted at each extreme of the sorted ratings was the largest integer less than or equal to the total number of ratings/4). All urgency ratings could, on average, be contained within 3.5 points on the scale, while the majority could be contained in less than two points on average. These results are displayed in Table 4.

TABLE 2—Influence of Panelists on Ratings: Regression Coefficients for Panelists with Least and Greatest Systematic Departure from Group Mean

	Level of pain syndrome*				
	1	2	3	4	5
Greatest Influence					
	−1.14	−0.84	−1.14	1.32	1.79
	0.66	0.82	1.31	1.79	0.84
	−0.93	−0.87	−0.47	−1.71	−1.42
Smallest Influence					
	−0.32	0.35	0.30	−0.31	−0.20
	0.07	0.27	0.14	0.24	0.11
	0.19	−0.04	−0.11	−0.31	−0.14
Standard Errors	0.12	0.11	0.13	0.11	0.14

*Levels of pain syndrome are in the same order as Appendix B. Note that a positive coefficient implies higher numerical score, i.e., less aggressive management; a negative coefficient has the opposite implication. Coefficients reflect influence within a model where, theoretically, the minimum value possible is 1.0 and the maximum is 9.0. However, no mean scenario rating was ever <2.0 and only a few within the mildest pain syndrome exceeded 8.5.

TABLE 3—Impact of Various Factors on Mean Ratings: Regression Coefficients

Chapter of questionnaire	1	2	3	4	5
Pain Syndrome (base case for other factors)*	8.01	7.09	6.98	4.19	2.83
Univariate Departures from Base Case					
Anatomy					
Left main disease	−2.57	−2.34	−2.06	−1.33	−1.05
3 vessel disease	−1.09	−0.53	−1.06	−0.57	−0.54
Left Ventricular Function					
Grade IV	0.08	0.10	0.28	0.77	0.73
Non-invasive Tests					
High risk	−1.34	−1.07	−1.20	NA	NA
Recent MI	NA	NA	NA	0.16	0.26
Previous CABS	NA	NA	NA	0.44	0.49
Median Panelist (absolute value)	0.55	0.33	0.49	0.40	0.31

Notes: Definitions for clinical factors are explained in Appendix B. The model presupposes a baseline case incorporating the pain syndrome. For pain syndromes corresponding to angina classes I-II, III, and IVA, the baseline anatomic factor is single or double vessel disease without left anterior descending arterial stenosis; left ventricular function is graded I-II; non-invasive tests suggest a low or average ischemic risk; and the expected procedural morbidity and mortality is low. For unstable angina without adequate symptomatic stabilization (classes IVB and IVC) neither non-invasive tests nor the distinction between left ventricular grades I and II apply, and the relevant base case is "No recent myocardial infarction" and "No previous CABS." All standard errors are approximately 0.10 (ranging between 0.05 and 0.14) except for Left ventricular grades I and II, where the standard error within angina class IVA is 0.19 in both cases. The coefficients for univariate changes in baseline factors illustrate their influence within a given pain syndrome.

TABLE 4—Widths of Ranges Encompassing Urgency Ratings in Isolation

Minimum number raters rating 1–7 for inclusion of the scenario	No Minimum	≥8 Raters	≥12 Raters
Number scenarios	438	392	327
Mean number rating "1"–"7"	12.85	13.84	14.65
Range (all raters)	3.55	3.69	3.72
Range (trimmed of high and low quartiles)	1.92	1.93	1.90
Mean residual number of ratings in trimmed result	7.12	7.59	7.95

Discussion

Although American[10] and British[11] RAND panels have previously graded the appropriateness of CABS, those evaluations were based upon 1981 indications, and involved ratings on a nine-point appropriateness scale—clearly distinct from our urgency scale with seven different time intervals and two appropriateness categories. It is nonetheless illuminating to compare similar agreement indices for our 16-person panel to those reported for the nine-person RAND panel. If unanimity is sought, the inter-practitioner agreement of the triage panel is about on a par with the first ratings of the RAND panel, and significantly lower than occurs with a second rating by the RAND panel once they knew their colleagues' ratings. However, in a comparison excluding extreme high and low ratings, agreement among the Ontario triage panel is superior to the first ratings and about on a par with the second ratings of the RAND panel (data available on request). This suggests an influence of outliers in the Toronto panel.

We have two suggested explanations for the outlier phenomenon. The first is that the structure of the scale may have been contributory. That is, outliers will be created when some panelists rate a scenario as relatively urgent (time-nodes 1 to 4) while others question the risk-benefit ratio and need for intervention (ratings 8 and 9). The second possibility is that a larger panel may increase the likelihood that one or more panelists will produce idiosyncratic ratings for any given scenario. We could not detect effects according to practitioner experience, site of practice (academic versus non-academic), or surgical versus cardiological orientation. However, the actual number of raters in any identifiable subgroup was small enough to limit our statistical power for detecting such effects.

Because our ratings reflect the initial clinical judgments of cardiologists and cardiac surgeons in the absence of knowledge about their peers' ratings, they offer an indication of the extent of inter-practitioner variation that might occur in actual practice. Moreover, inter-practitioner variation in ratings would be minimized by several features of the exercise followed here. All panelists practiced in urban centers, and were Canadian-certified specialists in cardiology or cardiac surgery. The majority did some specialty training at the University of Toronto, and practiced in or near Metropolitan Toronto. All received the same literature review summarizing how various factors influenced any time-dependent risk of death or myocardial infarction stemming from delay of mechanical revascularization. As already noted, all had agreed to the factors that were to be considered in rating case scenarios, and rated patients according to a standardized scale. All reviewed exactly the same case material, with none of the discrepancies that might occur in actual practice when different doctors assess patients and their test results. It is therefore very unlikely that the results of this exercise over-estimate the extent of inter-practitioner variation in managing this patient population. We suspect that larger discrepancies would be demonstrable on review of actual triage practices in Canada and other countries.

The magnitude of those discrepancies, as demonstrated here, is striking. Consider the following three examples from our results. First, even if agreement among a simple majority of panelists was accepted as reasonable, convergence on a single rating occurred in only 23 percent of scenarios. Second, if we divided the scale into three broad clinical categories—i.e. revascularize promptly, place on a waiting list, or do not plan intervention—only 11.4 percent of scenarios showed all 16 panelists agreeing within one of the three clinically pertinent categories. Third, even after eliminating disagreement about appropriateness of revascularization, the average difference between highest and lowest urgency ratings for the scenarios was 3.5 scale points out of a possible 7—corresponding to time differences ranging from two weeks for the most unstable patients, and on out to more than three months for those with stable angina.

In our view, these discrepancies are at odds with the aims of Canada's universal health care system. The architects of the Canadian health insurance system emphasized the concept of fairness, with the goal being that citizens should receive health services according to their needs.[12] A potential drawback to national health care systems is centrally constrained resources, with the substitution of rationing by queue for the rationing by price or income that occurs in settings of private prepayment for medical services; this criticism has been leveled against the British National Health Service.[13] However, one off-setting advantage of rationing by queue is that physicians are able to rank order patients in the queue according to judgments about the urgency of clinical need—arguably a fairer approach than priorities based on incomes or influence. Our findings raise the concern that this potential advantage is not being fully realized for coronary revascularization in the Canadian system.

While appropriateness issues were not the focus of this exercise, one logical line of attack on waiting lists is to ensure that all those waiting would indeed benefit from planned procedures. The CABS rates in Ontario have plateaued over the last several years. Anderson and Lomas have observed that the rates are being maintained largely by increasing application of CABS to patients over 65 years of age.[14] It is unclear whether the increasing use of CABS in the elderly represents an extension of utilization patterns to a group with a less favorable risk-benefit ratio, or an appropriate shift in utilization as the procedure becomes safer for elderly patients. The inter-rater disagreement on appropriateness ratings observed here suggests that a formal appropriateness panel may also prove worthwhile. In any event, creation of a fairer and more rational queue is a logical complement to any strategy that seeks to optimize resource utilization.

Despite the above-noted variations, at least three-fourths of panelists did agree within a three-point range on the urgency rating scale in over 80 percent of cases. When clinically pertinent categories were considered, any two randomly drawn panelists would rate scenarios in the same category two out of three times. Furthermore, weighed against the clinical variables, the panelists had much less importance as a determinant of ratings than such factors as severity and stability of anginal symptoms, non-invasive test results, or stenosis of major coronary arteries. In contrast, when Goyert, *et al*, examined practices of 11 obstetricians at a single hospital, only nulliparity exceeded practitioner identity as a risk factor for operative delivery.[15]

The revascularization panel's underlying agreement about determinants of urgency proved sufficient to permit a consensus on general principles governing triage of this patient population when the panelists convened in January 1989.[16] These guidelines are already being applied in a pilot Toronto program, were presented to a province-wide conference in November 1989, and will be undergoing further review by a multi-center working party during 1990. The ultimate goal is to standardize triage criteria voluntarily across the province so that inter-practitioner and inter-institutional discrepancies in waiting times can be reduced in the interests of fairness and efficiency.

ACKNOWLEDGMENTS

Our greatest debt is to the members of the expert panel (Appendix A). Dr. Naylor and Mr. Lomas are supported by Career Scientist Awards from the Ontario Ministry of Health. The Panel was convened under the auspices of the Metropolitan Toronto Cardiovascular Triage and Registry Program sponsored by: the Coronary Care Unit director's club of Metropolitan Toronto; the Metropolitan Toronto District Health Council; the divisions of cardiovascular surgery and cardiology of the Departments of Surgery and Medicine, University of Toronto medical faculty; and the Ontario Ministry of Health. The authors would like to thank Dr. Christopher D. Morgan for his useful comments.

Presented in part at the annual meeting of the Canadian Cardiovascular Society, Vancouver, British Columbia, October 27, 1989.

APPENDIX B

Factors and Levels Adopted by the Cardiology Panel for Patient Triage

A. Presenting pain syndrome and therapeutic response

1. Stable angina on reasonable medical therapy: mild to moderate [Canadian Cardiovascular Society classes I-II][17]
2. Stable angina on reasonable medical therapy: severe [Canadian Cardiovascular Society class III.][17]
3. Unstable angina, pain resolved with intensified medical therapy, and now on oral medication.
4. Unstable angina, symptoms improved but angina with minimal provocation.
5. Symptoms persisting or hemodynamically unstable, requiring coronary care monitoring and parenteral medication.

B. Coronary anatomy defined by angiography

1. Left main coronary artery stenosis with or without other stenoses.
2. Two or three vessel disease, *including* the proximal left anterior descending [LAD] artery or equivalent.
3. Three vessel disease *without* involvement of the proximal LAD artery.
4. Single vessel disease involving the LAD or equivalent vessel.
5. Single or two vessel disease *without* a proximal lesion of LAD artery or an equivalent vessel.

C. Expected procedural morbidity and mortality

1. High (e.g., renal failure, diabetes, peripheral vascular disease, chronic obstructive airways disease).
2. Average/Low

D. Reversible ischemia on non-invasive tests

1. *High risk:* e.g. poor performance on treadmill testing, with early and unequivocal ST-segment changes on electrocardiogram; thallium defects on exercise or dipyridamole stress testing involving either an extensive portion of the anterior wall or multiple areas.
2. *Low* risk: any test failing to meet the above criteria.

E. Left ventricular ejection fraction

1. >50%, approximately grade 1
2. 30/35%–50%, approximately grade 2
3. 20%–30/35%, approximately grade 3
4. <20%, approximately grade 4

F. Previous CABS: Yes/No

G. Myocardial infarction within previous 4 weeks: Yes/No

APPENDIX C

Urgency/Appropriateness Rating Scale Accepted by the Expert Cardiology Panel

1.	Emergency	Immediate revascularization
2.	Extremely urgent	Within 24 hours
3.	Urgent	24–72 hours
4.	Semi-urgent	72 hours to 14 days (same admission)
5.	Short list	2 weeks to 6 weeks
6.	Delayed	6 weeks to 3 months
7.	Marked Delay	3 months to 6 months
8.	Questionable if revascularization should be undertaken	
9.	Inappropriate for revascularization to be undertaken	

Note: Each urgency rating level represents the period within which revascularization is expected to be performed; the outer time limit for each limit represents the maximum acceptable waiting period for patients assigned that urgency rating.

APPENDIX D

Calculation of Agreement Indices

The agreement index was determined as in Davies and Fleiss[7] to calculate the probability that two panelists chosen randomly (without replacement) would agree on the rating of any scenario chosen with equal probability from all possible scenarios.

Thus, the $\binom{16}{2}$ pairings of raters were assessed for agreement on each scenario. Agreement was defined as either strict agreement on urgency scale, or agreement on the clinical categories "DO", "WAIT", and "NOT" (see text for definitions).

Hence, if $I_n(r_1, r_2) = 1$ for r_1 and r_2 agreeing on scenario "n" and 0 otherwise, then:

$$P_a = \frac{\sum_n \sum_{r_1<r_2} I_n(r_1, r_2)}{n\binom{16}{2}}$$

Note that "chance agreement" between two panelists is possible. This is calculated as

$$P_c = \frac{\sum_j \sum_{r_1<r_2} P_j(r_1)\, P_j(r_2)}{\binom{16}{2}}$$

where $P_j(r)$ is the marginal probability that the rating of panelist "r" is "j".

Thus, $P_k = \frac{Pa - P_c}{1 - P_c}$ is the chance corrected, or "kappa" agreement.

Note that kappa may be calculated either for each chapter or over all the scenarios, irrespective of chapter. The variance of the agreement indices is readily calculated and computed, but is unwieldy. (Available on request to author.)

Patient, Provider and Hospital Characteristics Associated with Inappropriate Hospitalization

ALBERT L. SIU, MD, MSPH, WILLARD G. MANNING, PHD, AND BERNADETTE BENJAMIN, BS

Abstract: To determine the relation between patient and provider characteristics and inappropriate hospital use, we examined adult nonpregnancy hospitalizations from a randomized trial of health insurance conducted in six sites in the United States. Appropriateness of inpatient treatment was based on medical record review; patient characteristics on sociodemographic, economic, and health status; and provider characteristics on descriptors of physician practice and hospital facilities.

Twenty-seven percent of admissions attended by physicians licensed for more than 15 years were judged inappropriate, compared to 20 percent for younger physicians. Admissions were more likely to be inappropriate if the patient was female (27 percent compared with 18 percent). Controlling for patient and provider characteristics reduces but does not eliminate the differences in the appropriateness of inpatient care across the study's six sites. Differences in available provider and patient characteristics do not account for geographic differences in inappropriate hospitalization in this study. (*Am J Public Health* 1990; 80:1253–1256.)

Introduction

As part of a wider concern for health care cost containment, recent attention has focused on the inappropriate use of hospital care. Recent studies have documented substantial inappropriate hospital use for adults, as well as children.[1–5] In the RAND Health Insurance Experiment, we reported previously that 23 percent of the admissions made inappropriate use of the acute hospital setting or level of care, while an additional 17 percent of admissions were avoidable by use of ambulatory surgery.[2] In this report, we examined the effect of patient, physician, and hospital variables on inappropriate hospitalizations and days. Our data provide some of the most detailed and comprehensive information available on the health status of patients.

Methods

The health insurance experiment was a randomized trial of cost sharing in health insurance conducted in six United States sites. Families entered the experiment between 1974–77 and were assigned to one of 14 different fee-for-service health insurance plans with different levels of cost sharing. The experiment excluded persons 62 years of age and older at the time of enrollment, those with incomes in excess of $25,000 in 1973 dollars, those eligible for Medicare disability, those in the military and their dependents, veterans with service-connected disabilities, and individuals imprisoned or institutionalized. Additional details on the design of the Health Insurance Experiment are available elsewhere.[6,7]

The sample of 3,413 individuals used as a basis for this analysis includes all enrollees who were 18 years of age or older at enrollment into the study. Medical records were obtained from 90 percent of the hospitalizations for these individuals. We excluded admissions for labor and delivery, psychiatry, and alcohol rehabilitation. This resulted in a sample of medical records from 1,132 admissions.[2]

To determine the appropriateness of hospital admissions or hospital days, two board-certified physicians reviewed medical records using the Appropriateness Evaluation Protocol.[3,8] They classified each admission or randomly selected hospital day into one of three categories: appropriate, inappropriate, or avoidable by ambulatory surgery. In this report, however, we considered admissions avoidable by ambulatory surgery as appropriate for two reasons. Ambulatory surgery centers were not available in all sites during the study period. Further, in Siu, *et al*,[2] the findings were not sensitive to whether ambulatory surgery was considered appropriate or inappropriate. Additional details on the review of hospital records for appropriateness are available elsewhere[2] or on request to the authors.

We use four groups of variables to explain the variation in inappropriate inpatient care: insurance plan, patient health status, patient sociodemographic and economic measures, and provider characteristics. We group the insurance plans into three groups: 1) the free plan (no out-of-pocket cost to the family); 2) the family cost sharing or pay plan, where the coinsurance rate is 25–95 percent for all services up to an upper limit on out-of-pocket expenses; and 3) the individual deductible plan with a 95 percent coinsurance rate for outpatient services (subject to an out-of-pocket limit) and free inpatient care. We use three measures of health status: 1) general health perceptions; 2) physical or role limitations; and 3) chronic disease status. Each measure is based on the self-administered Medical History Questionnaire completed at the beginning of the study. The General Health Index measures perceptions of overall health, as well as resistance to illness and health worry.[9,10] The physical or role limitations measure is scored dichotomously (1 = limited, 0 = otherwise) to indicate the presence of one or more limitations in self-care, mobility, physical activity, and usual role activities; the chronic disease measure is a simple count of the number of diseases or health problems.[11–14] The model used in our analysis also includes covariates for study site, patient age, sex, race, education, and family income and size. With the exception of family income, the data were collected before or at enrollment in the study (1974–77). Family income data are from 1975 in Dayton, 1978 for the three-year group in South Carolina, and 1976 for all other participants.

Variables describing the hospitals were obtained from the American Hospital Association files. This included information regarding accreditation, the presence of a residency program, medical school affiliation, ownership, number of beds, number of admissions, occupancy rate, and available facilities. Information on attending physicians was

obtained from the American Medical Association Directory of Physicians' Master File. For osteopaths, we obtained information from the Directory of the American Osteopathic Association. We located 95 physicians missing from these two sources by way of the computerized National Yellow Pages. For this latter sample of physicians, information on their characteristics was obtained from their practices by phone interview. These sources yielded information on physician sex, years from licensing, type of practice, practice arrangement, self-designated specialties, and board certification.

Although we obtained patient and hospital descriptors on all 1,132 admissions for whom medical records were available, some information is missing: nine percent for specialty, 12 percent for licensing, and 19 percent for solo/group practice data. Missing data were replaced by the mean value for that variable in regressions, and dummy variables were included to indicate cases with data missing for a given variable. The Appendix lists the independent variables used in this analysis and their means.

Statistical Methods

We used a logistic regression to estimate the probability that a particular admission or hospital day was medically inappropriate. The dependent variable in these regressions is whether the admission or day is inappropriate. For different groups (e.g., site, sex, specialty), we make both unstandardized and standardized comparisons. For the unstandardized comparisons, we predict the mean probability (and calculate its standard error) without correcting for the other differences between the contrast groups. For example, in comparing Seattle with one of the rural sites, we do not adjust for the differences in the mix of physicians or hospital types. We also estimate standardized predictions that remove the effects of factors confounded with the contrast of interest. For example, we want to purge the Seattle-rural site comparison of differences in patient and provider mix. To do this, we predict the probability that each admission or day is inappropriate if that case were in Seattle, then as if it were in Dayton, etc. This procedure is like the usual direct adjustment, except that it is based on the estimated model that controls for several factors simultaneously. All inference statistics are corrected for intratemporal correlation, as well as correlation among providers and family members.[15] We report standardized predictions and 95 percent confidence intervals (CI) for differences between categories of independent variables; p-values are reported in the text for the overall effect of statistically significant independent variables with multiple categories.

Results

As previously reported, we found that 23 percent of the adult hospital admissions were inappropriate and 35 percent of the days were inappropriate.[2] Logistic regression with hospital admission inappropriateness as the dependent variable showed that cost-sharing had no effect on the proportion of admissions that were inappropriate. However, there were differences by site ($p = 6.2 \times 10^{-5}$), gender, education ($p = 0.03$), hospital accreditation and bed size, and physician specialty ($p = <10^{-8}$) and length of time since licensing.

Unstandardized estimates showed that a greater likelihood of an inappropriate hospital admission was associated with a number of variables, but these differences could be due to the intrinsic differences among the groups compared or to other factors that differ among the groups. The standardized comparisons control for these other differences. The standardized predictions in Table 1 demonstrate that the proportion of admissions considered inappropriate are increased substantially if the physician was licensed more than 15 years ago or if the patient was female, and increased moderately if the attending physician was either an internist or a general/family practitioner.

Logistic regression showed that cost sharing had no effect on the appropriateness of a hospital day. Site differences persisted ($p = 0.03$) although they were smaller. Among the patient variables, only sex remained associated, and none of the hospital variables remained associated; years from licensing remained associated among the set of physician variables.

For unstandardized comparisons, the likelihood of a hospital day being inappropriate is increased if the physician was not board certified or was licensed more than 15 years ago, if the hospital was nonpublic, and if the patient was female. The standardized estimates (Table 2) are similar to those for inappropriate admissions although years from licensing and patient gender are more strongly associated and physician specialty less strongly associated.

There were substantial unstandardized differences across sites in the inappropriate use of inpatient care. In the case of both hospital admissions and days, the lowest proportion of inappropriate use is found in Seattle. Standardizing for patient, physician, and hospital variables reduced but did not eliminate the variation among sites in inappropriate use (Table 3). Addition of these explanatory variables reduced the variation resulting from site differences from 5.1 percent to 2.6 percent for hospital admissions and from 2.4 percent to 1.6 percent for inappropriate days. This is most

striking in the comparison of Georgetown and Seattle for hospital days, where a twofold unstandardized difference (42 compared with 21 percent; not shown) in inappropriate days was reduced by half (34 compared with 22 percent). Thus, although addition of patient, physician, and hospital variables decreased the extent of variation, significant geographic differences in the proportion of inappropriate hospital use remain even after controlling for these sources of variation with available variables.

Discussion

The sites in this study differed in patient characteristics and in provider types and availability, and we found that some of these characteristics were associated with inappropriate use. Nevertheless, we found that site differences in the proportion of inappropriate hospital use remain, even after controlling for most measurable aspects of patient, provider, and hospital characteristics. This finding confirms, for inappropriate hospital use, Wennberg's observation that practice patterns differ by geographic region and cannot be fully explained by geographic differences in patient or provider characteristics.[16]

The magnitude of these site differences was reduced by controlling for these patient and provider variables, some of which were strongly associated with inappropriate use. For both hospital admissions and days, we found that older physicians and female patients were more likely to be associated with inappropriate use. Although certain physician specialties were less likely to result in an inappropriate admission, these specialty differences in inappropriate use were most likely related to the performance of procedures. Many patients admitted by surgeons and gynecologists underwent a procedure within the first day of admission, leading the hospitalization to have been more likely designated appropriate for acute level care.

We cannot determine whether the effect of years from licensing is related either to declining clinical skills or to a cohort effect. Similarly, we are unable to explain the gender differences in inappropriate hospitalization. Gender effects have been observed in most studies attempting to explain overall patterns of medical care utilization.[17] The differences observed in our study could not have been due to child bearing, because pregnancy and related admissions were excluded from this analysis. This leaves a number of possible explanations, including differences in (a) how physicians perceive women's health needs, (b) the level of support available to women at home, and (c) the types of nonobstetric medical problems encountered by women.

Our results reaffirm the importance and policy significance of geographic variations in medical practice. The geographic variations observed in this study could not be attributed solely to patient and provider characteristics, many of which are difficult to modify. Future research should focus on the identification of modifiable variables and methods to reduce inappropriate hospital use.

Current cost containment policies are not likely to selectively reduce inappropriate hospital use,[2] and other approaches to do so are necessary. Retrospective review with feedback of results to physicians[18] may be one such approach. Conducting retrospective audits and making these results available to major buyers (e.g., major employers) is another approach to this problem. While it would be more efficient to target such reviews on those hospitalizations most likely to be inappropriate, our results suggest that targeting to specific physicians or hospitals on the basis of various characteristics would be very difficult. To reduce inappropriate hospital use by mechanisms involving targeted utilization review, other approaches to targeting will need to be developed.

Surveillance of Occupational Lung Disease: Comparison of Hospital Discharge Data to Physician Reporting

KENNETH D. ROSENMAN, MD, LINDA TRIMBATH, AND MARTHA STANBURY, MPH

Abstract: A survey of 762 New Jersey physicians showed that 35% reported seeing patients with either asbestosis, coal worker's pneumoconiosis, occupational asthma or silicosis. Three to four times as many patients with these diagnoses were seen as outpatients as were hospitalized. The implications of these results in using hospital discharge data for occupational disease surveillance are discussed. (*Am J Public Health* 1990; 80:1257–1258.)

Introduction

It has been proposed that hospital discharge data be used as part of an occupational disease surveillance system.[1,2] One of the limitations of hospital discharge data is the lack of information on non-hospitalized individuals. We conducted a survey of physicians in New Jersey to obtain estimates of how many patients they saw in their practice with asbestosis, coal workers' pneumoconiosis, occupational asthma, or silicosis in comparison to the number of patients they admitted to the hospital with the same diagnosis.

Methods

The names and addresses of physicians were obtained either from the state hospital discharge system or directly from the hospitals under state occupational disease reporting regulations (New Jersey Administration Code 8:57–1.13). Names and addresses of physicians were obtained by linking medical license numbers in the hospital discharge record to a data set of all licensed physicians in the state. The physicians surveyed had discharged at least one patient for the year 1985, 1986 or 1987 from one of New Jersey's 105 acute care (non-federal) hospitals with the diagnosis of asbestosis (ICD 501), coal workers' pneumoconiosis (ICD 500), pneumoconiosis due to other inorganic dust (ICD 503), pneumonopathy due to inhalation of other dust (ICD 504), pneumoconiosis unspecified (ICD 505), silicosis (ICD 502).

In the spring of 1988, a letter was mailed to these physicians requesting information about their medical specialty, an estimate of the total number of their patients newly diagnosed with asbestosis, coal workers' pneumoconiosis, occupational asthma, and silicosis in the calendar year 1987, and an estimate of the proportion of these patients admitted to the hospital during that same year. Non-respondents to a second and third mailing were contacted by telephone.

Results

A total of 847 physicians were included in the survey, of whom 762 (90.0 percent) completed the questionnaire. The reasons for non-response were: 29 (3.4 percent) letters were undeliverable; 20 (2.4 percent) refused to participate when telephoned; 11 (1.3 percent) were unreachable despite five telephone calls; nine (1.1 percent) had unlisted telephone numbers; six (.7 percent) retired; five (.6 percent) moved out of state; five (.6 percent) were deceased.

Table 1 shows the number of respondents, by medical specialty, who saw patients in 1987 with any of the lung conditions under consideration. The percentage of physicians reporting patients in 1987 is less than 100 percent, because many physicians may have had no patients with these diagnoses in 1987 or because they did not report all such patients.

Table 2 shows the proportion of patients hospitalized: for asbestosis 34 percent (95% CI = 31, 37); for coal workers' pneumoconiosis 26 percent (95% CI = 18, 35); for occupational asthma 23 percent (95% CI = 19, 27); for silicosis 27 percent (95% CI = 20, 35) were hospitalized. For all diseases combined, 548 (30 percent) of 1,814 patients (95% CI = 28, 32) were hospitalized.

Discussion

For the four diseases surveyed, physicians stated that for every patient hospitalized with the condition they had two to three additional patients with the same diagnosis who had not been hospitalized. This selected group of physicians reported nearly as many newly diagnosed cases of pneumoconiosis in New Jersey as are reported annually in the supplementary data system of the Bureau of Labor Statistics.[4] The number of additional patients not hospitalized varied both by disease as well as by the specialty of the reporting physician. The variation of hospitalization by specialty may be a reflection of the severity of disease seen by different physicians. For example, surgeons reported that 79 percent of their patients with asbestosis were hospitalized. The variation, however, may also reflect the relative amount of time physicians see hospitalized versus ambulatory patients.

None of the physicians reported their specialty as occupational medicine. Hospitalizations were not limited to a few specialty groups such as pulmonary physicians. Percentages of physicians reporting patients with lung conditions in 1987 by specialty varied from 8–79 percent although all physicians had admitted patients with these lung conditions

in 1985, 1986 or 1987. Efforts are underway to follow up this survey by encouraging the physicians to report the names of patients they estimated on the questionnaire. Similar surveys in other states will be useful to examine if there are differences in care patterns in different states.

The physicians response rate to the questionnaire was excellent. We attribute this to its briefness and to our only asking for estimates. This is also its major limitation as we did not evaluate the accuracy of the physicians estimates. According to statewide hospital discharge data for 1986, there were 881 patients discharged with asbestosis, 97 patients with silicosis, and 235 patients with coal workers' pneumoconiosis. For the first two diagnoses, the hospital discharges were less than those reported by the physicians; for coal workers' pneumoconiosis, the hospital discharges were more than those reported by physicians. No data on occupational asthma is available from discharge data.

If the percentages of underreporting of 67 to 75 percent for different diseases found in this survey is generalizable and reassessed by periodic surveys of physicians then hospital discharge data because of its relative ease of collection and low cost would be a useful method to examine trends and estimate the number of occupational pneumoconioses.

Recently, the National Institute for Occupational Safety and Health (NIOSH) has been promoting the concept of sentinel provider-based occupational disease surveillance systems.[3] This survey shows that hospital discharge data can be used directly or indirectly to identify names, addresses and medical specialties of potential sentinel providers, and that, with sufficient follow-up, these physicians are willing to report to a state health department information that can be relied on for occupational disease surveillance.

ACKNOWLEDGMENTS

We wish to thank all the physicians who took the time to respond to our questionnaire. We wish to acknowledge the assistance of Gwendolyn Solice-Sample and Ruth VanderWaals. This activity was funded under a National Intitute of Occupational Safety and Health Cooperative agreement.

Food-borne Outbreak of *Giardia Lamblia*

JOHN D.H. PORTER, MBBS, MPH, CAROL GAFFNEY, BSN, DIANNE HEYMANN, BSN, AND WILLIAM PARKIN, DVM, DRPH

Abstract: An outbreak of giardiasis occurred following a family party for 25 persons. Nine who had eaten fruit salad became ill, compared with one who had not eaten the salad (Relative Risk = 7.4, 95% CI = 1.4, 169.3). The fruit salad preparer had a diapered child and a pet rabbit at home who were both positive for *Giardia lamblia*. This outbreak emphasizes the importance of good hygienic practices in food preparation and the possibility of domestic-animal-to-person transmission in *Giardia* outbreaks. (*Am J Public Health* 1990; 80:1259–1260.)

Introduction

Giardia lamblia infection is often acquired by drinking contaminated water[1,2] or by person-to-person transmission among preschool children.[3] Transmission by food was first reported in 1981 when an outbreak of giardiasis was caused by eating contaminated home-prepared salmon.[4] We report an outbreak of giardiasis which most likely occurred due to the contamination of a fruit salad with *Giardia* cysts. The investigation also raises the question of whether domestic animals can play a part in transmission.

Background

On March 30, 1986, a party for 25 persons from seven separate family groups was held at a private home in southern New Jersey. Within seven days of the party, several attendees developed giardiasis. The outbreak was identified by the county health department from seven stool specimens received from ill attendees which were positive for *G. lamblia*.

Methods

All party attendees were contacted by telephone, and a questionnaire was administered. Guests were asked whether they had had a diarrheal illness, which of 30 possible food and drink items they had consumed at the party, and whether they had been in contact with day care centers or institutions for the handicapped. To determine if there was a widespread outbreak of giardiasis in the area, four local hospitals were contacted.

A case of giardiasis was defined as a person who had diarrhea (>3 stools/day) for >5 days with or without fever, *or* intermittent diarrhea >5 days (with or without fever) with two or more of the following symptoms: flatulence, nausea, malaise, or abdominal cramps.

Stool specimens were collected from all party attendees and from the children and staff at the local babysitting service which was attended by a diapered child who had been at the party. Specimens were examined for *Giardia* microscopically and enteric bacterial cultures were performed for *Salmonella*, *Shigella*, and *Campylobacter* on all persons with clinical symptoms. A stool specimen was also obtained from a pet rabbit in the home of the diapered child and examined for *Giardia* cysts.

The environmental investigation included an account of the preparation of the food and an investigation of the household water supplies using filters.

Results

Epidemiology

Ten cases of outbreak-associated giardiasis were identified. Nine (eight stool positive) of the cases had onset of symptoms during the period six to 12 days following the party and one case (stool negative) occurred 18 days after the party. Three community giardiasis cases were reported from the local hospitals for the previous five months.

Attack rates by gender and age groups were similar; each household had at least one member who was a case (Table 1). The attack rate for 20 persons who had eaten some food at the gathering was 50 percent compared to zero for those not eating. The five persons who had not eaten any food were excluded from further consumption analysis. Among those eating food at the party, those eating fruit salad were seven times more likely to have a case of illness than those who did not eat the salad (82 percent, 9/11 vs 11 percent, 1/9, RR = 7.4, 95% CI = 1.4, 169.3) (Table 2); nine of the 10 case-patients and all of the stool-positive cases had eaten fruit salad.

Laboratory

Stool specimens from eight of the 10 case-patients were positive for *G. lamblia;* all were negative for enteric bacterial pathogens. One of the two cases with negative studies for *Giardia* had been on metronidazole for 10 days.

Environmental

The fruit salad was prepared in the home of a woman who became ill nine days after the party. She had a two-year-old diapered child who, with four other children, was cared for by a babysitter during the day. Her child, who had eaten the fruit salad, had had no symptoms of gastroenteritis but had a positive stool for *Giardia* on the first specimen. The

four other children attending the babysitter's home and the babysitter's family were negative for *Giardia*.

Two days before the party, this diapered child had been given a pet rabbit as a present. The animal had been present in the kitchen when the fruit salad was being prepared. The rabbit was positive for *Giardia* (unspecified).

The salad was made two to three hours before being served. The fruit was either peeled or cut on a lucite chopping board and then placed in a plastic bowl with a lid.

No *Giardia* cysts were found in the filters from the homes.

Discussion

This outbreak of giardiasis represents a point-source outbreak with the fruit salad as the most likely vehicle of transmission. The high attack rate for those persons who ate the salad (82 percent, 9/11) implies that *Giardia* was effectively transmitted by this food.

The outbreak had some similarities with the salmon outbreak previously reported.[4] Both had high attack rates for persons who ate the contaminated food—48 percent for salmon and 82 percent for fruit salad—and, in both outbreaks, food was probably prepared without prior hand washing. Diapered infected children were present in both homes where the contaminated food was prepared.

There are two likely hypotheses for transmission of *Giardia* and both postulate that the fruit salad was contaminated by the food preparer who had failed to wash her hands before food preparation. The first hypothesis is that changing of the infected child's diaper would have been an effective way of transmitting cysts to a persons' hands and then to the fruit salad. Fruit salad contains a liquid acid medium which would maintain the viability of *Giardia* cysts which are known to be resistant to acid.[5] It is also known that cysts are rapidly destroyed when dried, but remain viable for weeks under moist conditions.[6]

The second hypothesis for transmission is that the rabbit was positive for *Giardia* when it entered the home and was excreting cysts. These cysts were transferred to the hands of the food preparer who contaminated the fruit salad by failing to wash her hands. There is one report of an outbreak of giardiasis in which transmission occurred between animals and humans in a zoo.[6] In addition, there has been a report that suggests that cats may be responsible for introducing giardiasis into households[7] but little is known about the importance of animals as reservoirs of the human *Giardia*[6] or the susceptibility of humans to animal *Giardia* (other than *G. lamblia*). Traditionally it has been believed that *Giardia* is highly host-specific.[8]

We recommend that when health department personnel investigate *Giardia* outbreaks, they should consider the possibility of food-borne transmission and when giardiasis occurs in a household that contains domestic animals, stool specimens should be collected from the animals for cyst microscopy. If possible, the human and animal species of *Giardia* should be determined. In this way, more information will be collected to determine if *Giardia* cysts are transmitted between domestic animals and humans.

ACKNOWLEDGMENTS

Leukemia Incidence and Radioactivity in Drinking Water in 59 Iowa Towns

LAURENCE FUORTES, MD, LOUISE ANN MCNUTT, MS, AND CHARLES LYNCH, MD, PHD

Abstract: Fifty-nine towns in Iowa with single source drinking water supplies were stratified on the basis of radium content in finished non-softened water to test the hypothesis of an association with total or acute myeloid leukemia. Fourteen towns had radium concentrations in drinking water exceeding the EPA safety limit of 5 picocuries per liter (pCi/L). A small increasing trend existed for total leukemia with increased radium content in drinking water that is in accordance with either the hypothesis of no effect or of a small effect. (*Am J Public Health* 1990; 80:1261–1262.)

Introduction

Several studies have documented increased cancer incidence or mortality associated with radioactivity of drinking water. The US Environmental Protection Agency (EPA) has set a safety limit of 5 picocuries per liter (pCi/L) for total radium in public water supplies. There are a number of communities nationwide whose water supplies exceed this limit. In a study reported in 1966 on low level radium 226 exposure, death rates from bone cancer were found to be higher in municipalities exposed to higher levels of radium 226 in drinking water. The numbers of cases were small, however.[1]

Ingested radium (Ra^{226} and Ra^{228}), an alpha particle emitter, is a well documented cause of bone and nasal cancers in studies of radium dial painters and follow-up of patients treated with Ra^{224}. In the radium dial painters, the risk of developing bone cancer was impressive in magnitude, (RR = 50), and specific to bone.[2] In the studies of human subjects treated with Ra^{224} (a shorter lived isotope), the risk of both bone cancers and leukemias was increased.[3]

A recent study from Florida revealed an association of acute myelogenous and total leukemia incidence rates with radium content in private wells. In that study, 27 counties were chosen based on their proximity to deposits of phosphate ore.[4] Based on a survey of 50 private wells in each county, 10 counties had high exposure and 17 had low exposure. Counties with greater than 5 pCi/L of radium in 10 percent or more of the sampled wells were included in the high exposure group. The age-standardized incidence density ratio for high exposure vs low exposure was 1.49 for total leukemia and 2.00 for acute myelogenous leukemia.

In a previous Iowa study, associations of radioactivity in drinking water were reported with lung, breast, and bladder cancer.[5] The Iowa data were reexamined in an attempt to determine if radioactivity in drinking water was associated with leukemia incidence.

Methods

Fifty-nine Iowa towns, each of less than 10,000 population, with a single source water supply and without water softening in their treatment process were identified from an Iowa Geologic Survey Bureau data base. The towns were stratified into three groups according to radium^{-226} content in finished water: *high* = Ra^{-226} greater than 5 pCi/L, *medium* = Ra^{-226} between 2–5 pCi/L, and *low* = Ra^{-226} less than 2 pCi/L. For each of the towns studied, there were greater than 2 radium measurements in finished water available. By this schema there are 812,616 persons years in the high, 2,055,060 in the middle, and 1,562,652 person years in the low exposure categories.

Identification of leukemia cases was performed by the State Health Registry of Iowa. Cancer incidence data were utilized for the years 1969–84, excluding 1972. There was no statewide cancer surveillance in 1972. Total and myelogenous leukemia rates are reported.

Age-adjusted, sex-specific incidence rates and 95 percent confidence intervals were calculated for each of the three groups using direct standardization as described by Fleiss.[6] The standard population utilized was the 1970 US population. Statistical testing for linear trend in incidence rates across the three groups was performed using a poisson trend statistic.[7]

Results

The age-adjusted incidence rates for total leukemia and acute granulocytic leukemia are shown in Tables 1 and 2. There was a weak positive relation between total leukemia rates and radioactivity in water, but a weak negative relation between acute granulocytic leukemia rates and radioactivity level consistent with either the hypothesis of no effect or of a small effect. As shown by the wide confidence intervals, the estimates of radioactivity-specific rates were rather unstable.

Group 3 = Low, RA-226 < 2.0 PCi/L, 27 towns with an average population = 4,154 for a total of 1,562,652 person years.

Discussion

These data do not support the strong relation between radioactivity in drinking water and leukemia incidence suggested by the Florida study.

Published studies on the association of radium in water with cancer are aggregate studies and subject to the biases associated with such designs. The results of the Iowa and Florida studies may to some extent be explained by misclassification and confounding.

In the case of water studies, a more accurate measure of exposure would be based on the amount of radium^{-226} water consumed by each individual and the examination and adjustment for confounding etiologic factors. The amount of radium^{-226} in drinking water in these communities is subject to a variety of factors including home water softening, varying tap water consumption, duration of residence in the community, and so forth.

In the Florida study, a county was defined as high exposure on the basis of 10 percent of the sampled wells exceeding the EPA limit for radium. The Iowa study has the benefit of accurately defined exposure categories in a demographically stable area. Despite similar study designs, this study does not yield the strong association previously reported with leukemia. Future study of cancer incidence and radium concentration in drinking water in these and other communities is needed to clarify the risk of leukemia secondary to naturally occurring Ra^{-226}.

Survey of Occupational Exposure of Waste Industry Workers to Infectious Waste in Washington State

WAYNE L. TURNBERG, MSPH, AND FLOYD FROST, PHD

Abstract: We surveyed 940 Washington state waste industry workers to evaluate occupational exposure to potentially infectious materials (response rate 47 percent). Only 26 percent were trained specifically to deal with safety hazards associated with medical waste. For the year preceding the survey, 50 percent of respondents reported having received cuts and scratches on the job, 22 percent reported direct contact with waste blood on their clothing or shoes, 8 percent had blood exposure on their skin, 3 percent blood exposure on their face or eyes, and 6 percent occupational hypodermic needlestick injuries (10 percent among waste collectors). (*Am J Public Health* 1990; 80:1262–1264.)

Introduction

Medical waste disposal has recently emerged as a concern for waste industry workers. The AIDS (acquired immunodeficiency syndrome) epidemic has elevated waste worker concern regarding the potential for disease transmission from medical waste stream sources. Such transmission of AIDS or hepatitis B has never been epidemiologically demonstrated.[1]

Few studies have been conducted to examine waste industry worker exposure to potentially infectious agents in the waste stream. Gellin and Mitchell examined 97 waste workers employed by the City of Cincinnati during January and February of 1968 for skin disorders.[2] Forty-one cases of bacterial, viral, or fungal dermatitis were observed in this group, but all were classified as non-occupational in origin.

Cimino examined New York City Sanitation Department health records of waste workers employed between 1968–69.[3] Needlestick injuries were reported due to the presence of uncontained needles in waste collected from hospitals, physician's and dentist's offices, and discarded needles from drug addicts. All workers reporting needlestick injuries were given

gamma globulin prophylaxis and no cases of hepatitis were reported.

A 1979 report by Clark, *et al*,[4] examined the incidence of viral infection among 43 waste collection workers. Sera antibody levels for 18 viruses were examined from blood samples collected during the spring and fall. The authors found no evidence of increased occupational risk to blood-borne viral infections.

This study was conducted to examine occupational exposure of Washington state waste industry workers to blood-contaminated waste and discarded hypodermic needles in the municipal waste stream.

Methods

The survey was conducted during February and March of 1989. Questionnaire packets were prepared and delivered to seven private sector waste industry firms and six public sector waste collection/disposal agencies. Selection focused on the state's population centers, although rural participation was included. Industry names were obtained through the Washington Utilities and Transportation Commission records and public sector solid waste utility listings. A total of 940 questionnaires were distributed to waste workers directly involved with waste collection or disposal within these firms or agencies. Based on the number of waste workers identified in the 1980 census which was adjusted for population growth and a review of non-participating firms, the surveyed workers account for approximately 70 percent of the waste industry workforce in Washington state.

Participant responses were confidential and not individually identified. Questionnaires were returned directly to the research group by the participants in stamped return envelopes without review by their respective waste industry employers.

Participants included those involved with residential waste collection, commercial collection, and landfill/transfer station operations. Waste worker job categories included heavy equipment operators, truck drivers, collectors, equipment maintenance personnel, laborers, recyclers/sorters, gatekeepers/scalehouse operators, and field supervisors.

Survey variables included the respondent's job category, job safety training, occupational observance of medical waste, exposure to blood-contaminated waste, and occurrence of hypodermic needlestick injuries. Questions regarding occupational exposures or injuries requested that the respondent include the month and year of his/her most recent event to discourage a positive response unless a specific occurrence could be recalled.

Results

Of 940 surveys distributed to waste workers, 438 were returned (47 percent). Of these, 52 percent of respondents conducted all or part of their job activities in residential waste collection, 41 percent in commercial waste collection, and 38 percent in landfill/transfer station operations.

Sixty-nine percent of the respondents reported receiving job safety training. Twenty-six percent indicated that this training included medical waste safety practices. Ninety percent of the respondents reported observing medical waste (e.g. needles, blood, bandages) in the waste stream. Of this group, the frequency of observation of medical waste was identified as daily by 27 percent of this group, weekly by 40 percent, monthly by 17 percent, yearly by 8 percent and less than once a year by 8 percent.

Injury/exposure information for occupational cuts and scratches, blood exposures, and needlestick injuries is based on the respondent's recall for events occurring on at least one occasion. Such information reported for the year preceding the survey required the respondent to include both the month and year of their most recent event.

Cuts and scratches received on the job were reported by 74 percent of the respondents. For the year preceding the survey, such injuries were reported by 50 percent of respondents.

Thirty-two percent of the respondents reported having experienced direct contact with blood on their clothing or shoes, 13 percent on their skin, and 5 percent on their face or eyes. For the year preceding the survey, 22 percent reported having experienced direct contact with waste blood on their clothing or shoes, 8 percent had blood exposure on their skin, and 3 percent had blood exposure on their face or eyes.

Twenty-one percent of responding waste workers reported having been stuck or scratched by a waste hypodermic needle. Six percent reported that their most recent injury occurred within the year preceding the survey. Such injuries were reported by 10 percent of waste collectors within the same time period. Needlestick injuries were reported by 24 percent of respondents for residential waste collection, 21 percent for commercial waste collection, and 11 percent for landfill/transfer station operations. Needlestick events by individual job category are presented in Table 1.

Discussion

In this survey, the low response rate (47 percent) may have resulted in a higher estimated incidence of exposure; exposed individuals should be more likely to respond if an exposure is a memorable experience. If one assumes that none of the non-responders had experienced an exposure and only respondents who could give both the month and year of the event actually experienced an exposure, the estimated exposure incidence among the 940 persons sent a questionnaire for the year preceding the survey would be 10 percent (blood exposure to clothing or shoes), 4 percent (blood exposure to skin), 1.5 percent (blood exposure to face or eyes), and 3 percent (needlestick injuries).

Of greatest potential significance to waste worker health was the reporting of needlestick injuries. Written survey comments from workers described loose needles originating from uncontained disposal or ruptured sharp containers in the waste stream. Needles were identified originating from both residential and medical facility sources. Accounts of uncontained

TABLE 1—Needlestick Injury by Waste Worker Job Category for the Year Preceding the Survey

*Needlestick response requires respondent noting month and year of occurrence.

needles and the reporting of needlestick injuries sustained by waste workers indicate the need for proper handling, containment and/or destruction of needles by users prior to disposal.

Observation of medical waste (e.g. needles, blood, bandages) in the general waste stream was common (90 percent of respondents). Further study to identify frequency of occupational exposure to blood is recommended, especially in relation to proposed standards for bloodborne pathogens by the US Department of Labor, Occupational Safety and Health Administration.[5]

Fear of AIDS and Attrition among Medical Technologists

RONALD R. GAUCH, PHD, KAREN B. FEENEY, MPA, AND JAMES W. BROWN, PHD

Abstract: Attitudes toward AIDS were measured by a survey of 212 attendees at the annual meeting of the New Jersey Society for Medical Technology. Twenty five percent of the respondents were considering leaving the profession because of a fear of AIDS. In addition, almost half would not have chosen the field knowing they would be handling HIV-positive samples. This high degree of concern may be an important factor contributing to the shortage of medical technologists. (*Am J Public Health* 1990; 80:1264–1265.)

Introduction

A 1988 survey by the American Society of Clinical Pathologists reported that 9 percent of medical technologists positions are vacant and more than 75 percent of laboratory managers perceive a shortage of qualified laboratory personnel.[1] The shortage among medical technologists has been attributed to a wide spectrum of problems: low pay with a compressed salary structure, lack of upward mobility, job stress, poor working conditions, lack of professional recognition, and increased opportunities in other professions that have commensurate educational requirements.[2,3]

A survey conducted in 1987 among New England laboratories, reported that 39 percent of the respondents mentioned fear of AIDS (acquired immunodeficiency syndrome) as a reason laboratory workers leave the profession.[4] A 1987 study, confined to medical technologists, also found a high fear of acquiring AIDS.[5] The purpose of our study was to describe attitudes of medical technologists toward working with AIDS-infected samples.

Methods

A questionnaire was designed which included 15 questions using Likert rating scales with the response options ranging from strongly agree to strongly disagree. Independent variables included demographic and institutional factors. Three additional questions dealt with an individual's knowledge of AIDS.

The questionnaire was distributed to registrants at the 1988 annual meeting of the New Jersey Society for Medical Technology. Of the 295 registrants, 283 were given forms to be filled out anonymously and 212 were returned (75 percent).

Results

The results showed that fear of AIDS among laboratory workers is common (Table 1). For example, 52 percent agreed with the statement that, despite precautions, it was likely that they could become infected with HIV because of laboratory exposure and 41 percent would like to transfer to a position that required less blood handling. Only 43 percent indicated that they would have chosen the profession knowing they would be handling samples from AIDS patients and one out of four respondents is considering leaving the profession because of a fear of AIDS.

Medical technologists are clearly experiencing pressure to seek a different career. In 86 percent of those queried, respondents reported that friends and family members expressed concern about their working with HIV samples and 53 percent knew of colleagues who had left the profession because of the possibility that they could acquire the human immunodeficiency virus (HIV).

On the other hand, there was general satisfaction with employer safety policies. Three out of four felt their employer provided adequate education concerning HIV risk and that adequate safety measures, which lower the risk of HIV transmission, were available. However, less than half felt that their employer offered adequate counseling in the event of an accident.

It was apparent that the AIDS problem had resulted in improved safety practices within the profession. For example, increased reporting of needlestick injuries and the wearing of gloves were reported by 87 percent and 94 percent of the respondents, respectively.

Not surprisingly, those currently working were more inclined to contemplate a career change than people about to enter the field. One in three of employed medical technologists was thinking about departing the profession because of their fear of AIDS. In contrast, only 13 percent of the students surveyed indicated they were planning to take such a step.

TABLE 1—Percent of Respondents in Agreement with Survey Questions

Questions	Percent Agreement*
Fear of Acquiring AIDS Questions	
I feel I have the right to be informed of HIV + samples.	96
I believe that fear of acquiring HIV is a major reason for the low enrollments in the MLT and MT schools.	77
Despite precautions, I believe it is likely I could become infected with HIV because of laboratory exposure.	52
In retrospect, I would have chosen the field of medical technology knowing that I would be handling samples from AIDS patients.	43
I would like to remain in the field but would like to transfer to a position that requires less blood handling because of my fear of acquiring AIDS.	41
I am considering leaving the profession because of my fear (and/or my "significant other's" fear) of acquiring HIV in the laboratory.	25
Pressure to Leave the Profession Questions	
I have had friends or family express concern about my working with HIV positive samples.	86
I know of colleagues who have left the clinical laboratory profession because of their fear (and/or their "significant other's" fear) of acquiring HIV in the laboratory.	53
Employer Safety Policies Questions	
I feel that infection control practices in my lab have improved because of fear of acquiring HIV.	79
I feel my employer provides adequate education on HIV risk.	77
I feel my employer has provided adequate safety measures that lower the risk of HIV transmission in the laboratory.	75
I feel my employer offers adequate counseling in the event of an accident with HIV positive samples.	41
Employee Safety Practices Questions	
Because of the risk of contracting AIDS I am more likely to wear gloves today than in the past.	94
Because of the risk of contracting AIDS, I am more likely to report needlestick injuries than in the past.	87
I feel that universal blood precautions will change the way I currently handle samples.	72

*Percent based on a response of strongly agree or agree.

Further analysis was carried out on the group working in the field to determine if there were any important differences between those considering and those not planning a career change. No important differences were present in respect to age, sex, salary level, marital status, responsibility for dependent children, education level, or working environment (hospital or nonhospital work). Furthermore, the two groups were similar in respect to their knowledge of AIDS (i.e. awareness of the transmission, etiology, and diagnosis of AIDS). The only demographic variable that distinguished the two groups was position in the organization. Of those with supervisory responsibilities, 18 percent were considering a job change versus 38 percent of those without supervisory responsibilities (data available upon request to authors).

Discussion

These findings suggest that fear of acquiring AIDS contributes to the attrition rate among medical technologists. On a positive note, it was found that medical technologists tend to be satisfied with employer AIDS policies. There was, nevertheless, concern on the part of a majority of workers about the lack of a counseling program in the event of a laboratory accident. Employers can help reduce this anxiety by having counseling programs in place and making sure workers know they exist.

The survey found that because of AIDS, glove use increased substantially. However, when asked how often they wear gloves, only 46 percent responded that they wore gloves all the time. It therefore appears that laboratory management needs to be more active in motivating their staffs to wear gloves on a regular basis. The Occupational Safety and Health Administration's mandate for routine glove use, which came out after the survey was completed, places an even greater responsibility on the part of management to see to it that employees use safe practices.

It is also important to note that universal blood precautions, where all samples are to be considered infectious, were in effect when the survey was taken. Still, the overwhelming majority of the respondents (96 percent) felt they had the right to be informed of HIV positive samples. This situation illustrates a common dilemma facing the health care community—a patient's right to privacy and an employee's "right to know."

Are Women Using Postmenopausal Estrogens? A Community Survey

ROBIN B. HARRIS, PHD, AMI LAWS, MD, VENUGOPAL M. REDDY, MBBS, ABBY KING, PHD, AND WILLIAM L. HASKELL, PHD

Abstract: Self-reported estrogen and progestin use in a California community was determined in 1986–87 from a telephone survey of postmenopausal women (n = 954) ages 50–65 years. Current use of hormones was reported by 32 percent; 26 percent took estrogens alone while 6 percent used estrogen + progestin. Comparisons pointed to significant social network and medical care utilization differences. Women who used estrogen therapy were younger, thinner, lived in smaller household units, and were less likely to be widowed. (*Am J Public Health* 1990; 80:1266–1268.)

Introduction

Postmenopausal estrogen use has fluctuated in the past three decades, based on changing perceptions of its associated risks and benefits.[1–11] Currently, estrogens are advocated[12] because of their beneficial effect on serum lipids[13–16] and their protective effect against osteoporosis[10,11] and cardiovascular disease,[17–22] although the risk of cancer with prolonged use remains a concern.[3,8,9,23] Several studies have examined the effect of these changing perceptions on clinical practice.[24–26] Physicians in the mid-1980s report prescribing postmenopausal estrogen to far more of their patients than in the 1970s, although they are prescribing lower doses with an added progestin.[25,26]

We report postmenopausal hormone use in a defined community in 1986.

Methods

Between October 1986–April 1987, a random-digit dial telephone survey was completed of persons ages 50–65 years residing in Sunnyvale, California, a relatively affluent community located at the southern end of the San Francisco peninsula. Only one individual per household was interviewed, with decisions as to whom to interview made using a random allocation procedure. At least five calls were attempted to the household. The phone company estimates that over 97 percent of the households have telephones. The response rate among age-eligible women was over 72 percent.

Postmenopausal women were asked whether they were currently using any prescribed medications and to name the specific medications and dose by reading from the prescription labels. Hormone use was classified by major type of therapy: use of estrogens alone versus use of estrogens plus a progestin. Other questions, adapted from the 1985 National Health Interview Survey,[27] determined social and demographic characteristics, use of other medications and alcohol, exercise and smoking behavior, a brief medical history, and perceptions of current health status. Body mass index (kg/m^2) was calculated from self-reported height and weight.

This report is based on 954 postmenopausal women between ages 50–65 years. Only 45 women were excluded because of missing information on menopausal status or medication use.

Bivariate contingency tables were constructed to assess association between use of estrogens and the interview questions. Multivariate analyses used the logistic model to assess independence of the variables. Adjusted odds ratios and their 95% confidence intervals for estrogen use were calculated from the logistic coefficients and their standard errors[28] and to test for statistical significance of age interaction terms.[29] The dependent variable was coded as use or nonuse of estrogen hormones. Age and body mass index were modeled as continuous variables. Number of members in the household was an ordinal variable coded 0–6+; other independent variables were coded as presence or absence of the history or event.

Results

In this population, 32.2 percent (n = 307) of the women reported current use of postmenopausal estrogens. Of the 307 users, 18 percent (5.9 percent of the total population) reported also taking a progestin. Use was highest in the younger women, with 40.6 percent of women ages 50–54 reporting use compared to 23.1 percent of women ages 60–65 years. The use of progestins also decreased with age, from 9.4 percent of women ages 50–54 years to 2.8 percent of women 60–65 years.

Eighty-three percent of the hormone users identified a specific medication, or a dose if the estrogen was a generic conjugated estrogen. Premarin was the predominately named estrogen (65 percent), followed by the generic conjugated equine estrogens (27 percent). Forty percent of conjugated estrogen users named the .625 mg dosage. Provera accounted for 63 percent of progestin use, with 46 percent of these users naming the 10 mg dose.

Self-reported demographic and health behavior characteristics are shown in Table 1. Users were thinner, reported more regular aerobic exercise, had fewer people living in their households, and were less likely to be a widow than were the nonusers.

There were no differences between users and nonusers in their history of high cholesterol, diabetes, or heart problems (Table 2). Users were less likely to have a history of high blood pressure or stroke, but more frequently reported being under the care of a physician for other medical conditions.

Table 3 shows the results of the multivariate analyses. Age of the woman, body mass index, number of individuals in the household, and widowhood remained independent correlates of postmenopausal hormone use. Other logistic regression models showed history of high blood pressure, aerobic exercise, and presence of other medical conditions were not independently related to the hormone use. In addition, no significant age interactions were demonstrated. Similar analyses were performed to compare estrogen-only use with estrogen + progestin use; age was the only variable independently related to estrogen + progestin use.

TABLE 1—Descriptive Information on Sociodemographic and Health Behavior Variables for Users and Nonusers of Postmenopausal Hormones in the Sunnyvale Population, 1986

Characteristics	Postmenopausal Hormone	
	Users n = 307*	Nonusers n = 647*
Marital status		
% Married	59.6	59.8
% Widowed	9.1	14.9
% Currently employed	61.2 (304)	58.6 (642)
Education, mean ±sd	13.7 ± 2.6	13.6 ± 2.8
Ethnicity: % White	91.9	88.4
Household size, mean number ± sd	2.0 ± 0.8 (295)	2.4 ± 1.2 (628)
% Current smoker	24.6	26.7
% Aerobic exercisers	23.5 (302)	17.5 (642)
Body Mass Index, mean kg/m^2 ± sd	24.0 ± 3.9 (306)	25.4 ± 4.9 (631)
Alcohol use, mean drinks/2 weeks ± sd	10.4 ± 14.1 (240)	8.5 ± 10.9 (428)

*Total number of users and nonusers, if number different than given in parentheses.

TABLE 2—Self-reported Medical Conditions of Users and Nonusers of Postmenopausal Hormones

Characteristics	Postmenopausal Hormone			
	Users		Nonusers	
	%	N	%	N
History of high blood pressure	28.0	(304)	37.2	(645)
History of stroke	00.3	(307)	3.1	(646)
History of high cholesterol	21.8	(294)	20.6	(622)
History of diabetes	3.2	(285)	5.5	(599)
History of heart problems	6.2	(307)	6.2	(638)
Other medical conditions	23.7	(304)	18.1	(643)
Hospitalizations in past year, mean ± sd	0.2 ± 0.5	(298)	0.2 ± 0.6	(630)
Perceived health rating* mean ± sd	1.8 ± 0.7	(307)	1.9 ± 0.8	(646)

*Health rated as Excellent (1), Good (2), Fair (3), Poor (4).

TABLE 3—Adjusted Relative Odds for Postmenopausal Estrogen Use by Behavioral, Sociodemographic and Reported Medical Conditions

Characteristic	Adjusted* Odds Ratio	(95% CI)
Age trend per year	.92	(.89, .95)
Body mass index trend (kg/m^2)	.93	(.90, .97)
Household size trend (no./household)	.66	(.55, .78)
Widowed	.49	(.30, .82)

*Adjusted using a logistic regression model that included the variables listed on this table, n = 294 users and 612 nonusers.

Discussion

This 1986 community survey shows self-reported current use of PMH (32 percent) is less than expected when compared to recent physician surveys indicating 75–95 percent of gynecologists would prescribe estrogen therapy to most of their patients[25,26] and to estimates from pharmaceutical marketing surveys of 43 percent use among women living in the western part of the United States.[7] The use rate is similar to a recent report from another California community.[30] The use of progestin combined with the estrogen is also less than expected and less than previously reported,[30] with 18 percent of the users reporting a progestin component.

While response bias, i.e., women not knowing or remembering what medications they are currently taking, could have contributed to the low postmenopausal hormone use, it is unlikely to be the major explanation of these discrepancies. Over 80 percent of the estrogen users were able to name their specific medication and dose. Since hysterectomy status was not ascertained in this survey, it is impossible to know what percent of women with an intact uterus were using unopposed estrogens. However, this limitation would not have contributed to an underestimate of total use. A high hysterectomy rate in Sunnyvale could explain the lower use of progestins than seen in the Rancho Bernardo study.[30]

The taking of PMH by women is the outcome of several factors, notably: local physician prescribing practices, medical care utilization patterns, drug side-effects, and social network or information sources of the women. Differences between women who use and do not use estrogens can, therefore, be due to underlying social or behavioral differences as well as to actual drug effects.

As in other surveys,[31,32] the youngest women, who were most likely to be recently menopausal, had the highest current estrogen and progestin use. This pattern probably reflects the effort to control menopausal symptoms as well as to decrease bone density loss. Younger women reached menopause at a time physicians were increasing their postmenopausal hormone prescribing.

The findings of thinner women more likely to use hormones was also shown in the earlier surveys.[31,32] This difference may reflect increased menopausal symptoms in thinner women due to their decreased endogenous estrogen levels, or more prescribing by physicians because of increased risk of osteoporosis in thinner women.

Women who were widowed were less likely to be on estrogen therapy than women who were currently married, but women who used hormones had fewer people living in their households. These findings may reflect basic social network differences between users and nonusers: e.g. nonusers may be major caretakers of other family members and less likely to have the time or inclination to care for themselves; a recent study of persons over age 65 reported that people who live with others go to doctors less often.[33]

In summary, this survey shows a discrepancy between published physician enthusiasm for PMH and low reported use by women. Comparisons between users and nonusers reflect differences in physician prescribing patterns, social networks, and health care utilization patterns.

Estimating the Mortality Cost of AIDS: Do Estimates of Earnings Differ?

CHARLES E. BEGLEY, PHD, MARTIN M. CRANE, PHD, AND GRADY PERDUE, PHD

Abstract: The future earnings of male Texans dying of AIDS in 1987 were estimated using: national earnings profiles; earnings derived from occupations listed on death certificates; and earnings reported by persons with AIDS who responded to a survey. Mortality cost estimates using the two sources of actual earnings differed by a modest amount in comparison to the estimate using national earnings profiles. (*Am J Public Health* 1990; 80:1268–1270.)

Introduction

Because of the relative youthfulness of persons with acquired immunodeficiency syndrome (AIDS), the cost to society from the loss of earnings of those who die prematurely is an important concern in measuring the impact of the disease. Two published studies have attempted to determine this cost using the foregone earnings approach. Hardy and coworkers estimated the present value of the foregone earnings of the first 10,000 AIDS cases at $4.6 billion, over three times their estimate of total hospital expenditures (approximately $1.4 billion) for these cases.[1] Scitovsky and Rice estimated the current value of foregone earnings associated with AIDS deaths in 1986 at $6 billion, approximately six times their estimate of personal medical care costs ($1.0 billion).[2]

These estimates may be criticized because of the absence of actual earnings data in estimating the present value of future earnings lost. The foregone earnings method uses national cross-sectional profiles of earnings and labor force participation rates by age and sex.[3] It is simply assumed that a person with AIDS has the same employment and earnings pattern as other Americans in his or her age and sex cohort.

This paper examines this assumption by comparing estimates of the foregone earnings of males who died of AIDS in Texas in 1987 using national earnings profiles and two sources of actual earnings.

Methods

To derive the first estimate, we followed the standard practice of multiplying the present values of lifetime earnings

by age category, derived from national earnings profiles, by the corresponding number of AIDS deaths in Texas and summing the products across categories. The present value of future earnings by age, reported by Scitovsky and Rice for 1984,[2] were updated using the ratio of mean earnings for full-time workers in 1987[4] as compared to those in 1984.[5] The age characteristics of males who died of AIDS in 1987 were supplied by the Texas Department of Health.

The occupational status (obtained from death certificates) of a 10 percent random sample (N = 96) of males who died of AIDS in 1987 was the basis for the second estimate of mortality costs. The occupations of these persons were translated into average annual earnings using occupation-specific wage data for the Houston and Dallas-Ft. Worth SMSAs from the Bureau of Labor Statistics, US Department of Labor.[6,7]

The third estimate used earnings derived from a statewide survey of living persons with AIDS.* In the summer of 1988, a convenience sample of 1,083 persons with human immunodeficient virus (HIV) infection being served by community-based AIDS service organizations, physicians' offices, and other service providers were asked to complete an anonymous, self-administered questionnaire. The questionnaire requested information on occupation and income at the time of first HIV-related diagnosis. Forty percent (434) of the questionnaires were returned; 280 respondents (six females, 274 males) had an AIDS diagnosis. These individuals represented about 15 percent of all AIDS cases estimated to be alive in Texas at the time of the survey. Of the male respondents with AIDS, 228 (83 percent) supplied income information. Since the survey excluded persons outside the larger metropolitan areas of the state, illiterate and/or poorly educated individuals, and Spanish-speaking persons, it does not represent the state as a whole.

Mean earnings for males with AIDS in different age groups was derived, based on each source of actual earnings. Comparisons were made with national mean earnings reported by the Bureau of Census.[4] Percentage differences for each group were calculated and used to adjust the present value of expected lifetime earnings for the corresponding group. The adjusted earnings figures were then multiplied by the number of AIDS deaths in Texas in 1987 by age category and summed across categories to obtain mortality cost estimates. The cost estimate effect of each data source was subjected to sensitivity analysis to allow for errors in the estimates of actual earnings.

TABLE 1—Comparison of Age, and Occupational Characteristics: Survey Sample, Death Certificate Sample, and Case Registry

Characteristics	Information Source: Survey (N = 228) %	Death Certificates (N = 96) %	Texas AIDS Case Registry, 9/2/88 (N = 4926) %

[a] Foregone earnings based on national, survey, and death certificate estimates of current earnings: $743.4 million, $697.2 million, $656.4 million. Ten percent variations in the current earnings estimates produced foregone earnings ranging from $627.5 million to $772.4 million.
[b] Source: Reference 4.
[c] The national data include ages 18–24.

Results

Although obtained in different ways, the survey and death certificate samples were not significantly different from the Texas AIDS case registry with respect to age (Table 1). However, Blacks were underrepresented in the survey sample and Whites were overrepresented. There were more individuals with low wage occupations in the survey than in the death certificate sample.

The average annual earnings of male persons with AIDS in Texas, based on the death certificate sample, was 11 percent below the national average (Table 2). However, it was .3 percent above the national average when based on the survey sample.

The present value of lifetime earnings lost for male AIDS deaths in 1987 was $743 million based on national earnings profiles, $697 million based on earnings from the survey, and $656 million based on earnings derived from the death certificate sample. The two estimates using actual earnings were below the national earnings estimate by 6 percent and 12 percent, respectively. Given the possibility of error in the sample estimates of actual earnings, mortality costs were recalculated using earnings of 10 percent above and below the sample estimates for each age group. These variations lead to differences in mortality cost estimates ranging from 4 percent above to 15 percent below the national estimate.

Discussion

The mean earnings of male Texans with AIDS, based on occupational status, was found to be 12 percent below the national average. However, self-reported earnings from a sample survey averaged less than 1 percent above the national average. It is possible that bias in the survey sample could account for the difference. As noted earlier, it is likely that the survey sampling procedure reduced participation by individuals at the lower end of the income spectrum.

The effect of using the two sources of actual earnings rather than national earnings to estimate future earnings lost was a relatively small reduction. The differences remained relatively small after increasing and decreasing actual earnings estimates by 10 percent. This finding suggests that the additional effort required to obtain actual earnings for persons with AIDS in order to calculate the foregone earnings of premature mortality was not necessary in this case. However, further studies are needed to determine if the findings hold in less biased samples in other areas of the country and for the changing AIDS population.

Sociodemographic Correlates of Neutralizing Poliovirus and Hepatitis A Virus Antibodies as Markers of Different Modes of Acquiring Immunity

MANFRED S. GREEN, MD, PHD, DANI COHEN, MPH, RAPHAEL SLEPON, BSC, RACHEL HANDSHER, MSC, YONA ZAAIDE, BSC, LOTTE RANNON, MD, AND YEHUDA DANON, MD

Abstract: The prevalence and sociodemographic correlates of antibodies against poliovirus and hepatitis A virus (HAV) were compared in a random sample of 457 military recruits in Israel inducted during 1987. Lower socioeconomic status (SES) was associated with a higher prevalence of anti-HAV antibodies (67.3 vs 32.5 percent), whereas the reverse was true for type I poliovirus (78.4 vs 89.5 percent). While the high prevalence of anti-HAV antibodies observed in the lower SES groups reflects considerable natural exposure to enteroviruses, immunity against poliovirus appears to be determined primarily by compliance with vaccination. (*Am J Public Health* 1990; 80:1270–1271.)

Introduction

Between 1961–83, the annual incidence of poliomyelitis in Israel ranged from three to 35 cases.* It was felt that the population should have high levels of immunity through vaccination, but enhanced immunity acquired through continuous exposure to wild virus in the environment was also considered possible. Both the hepatitis A virus (HAV) and the poliovirus are transmitted by the fecal-oral route. Ethnic and educational differences in HAV infection have been demonstrated in Israel[1,2] and elsewhere.[3] We compared the sociodemographic correlates of antibodies against both HAV infection and poliomyelitis as markers of the modes of acquiring immunity to these diseases.

Methods

Sera stored at −20°C which had been taken from a random sample of 494 military conscripts in Israel in 1987 were used for the serological studies.

Sociodemographic data included age, country of origin, education and socioeconomic status (SES). Country of origin was defined by the father's birthplace (or where this was Israel, the paternal grandfather's birthplace). Those from Europe (excluding Turkey), the Americas, Australasia and Southern Africa were defined as Westerners. All other birthplaces, except Israel, were classified as Easterners. To simplify the classification, those whose father and paternal grandfather were born in Israel were excluded from the analyses, leaving a sample size of 457.

The normal approximation was used to compute 95 percent confidence intervals for difference between percentages. Multiple logistic regression analysis was used to determine correlates of antibodies while controlling for other potentially confounding factors.

Hepatitis Serology

The anti-HAV antibody studies were performed at the central Israel Defense Force laboratories by means of solid

phase radioimmunoassay (HAVAB-Abbott Laboratories, N. Chicago, IL).

Polio Serology

The neutralizing poliovirus antibody studies were carried out at the Israeli Central Virology Laboratory. The sera were inactivated before testing in a microneutralization system. Serial four-fold dilutions were prepared in microtiter plates and between 30 and 100 TCD_{50} of wild poliovirus (Mahoney--type 1, MEF—type 2, Saukett—type 3) were added. The mixtures were incubated at 36°C for 20 hours, followed by the addition of Hep-2 cells. Following incubation, fixation, and staining, the plates were examined macroscopically and titers were defined as the highest dilution of serum that completely inhibited cytopathic effect. In this study, antibody titers greater than 1:4 were regarded as positive. Since large inter-laboratory differences have been demonstrated,[4] caution should be exercised in comparing these titers with those obtained in other laboratories.

Results

The prevalence of anti-HAV antibodies was substantially lower for Westerners (30.9 percent of 201) than for Easterners (57.0 percent of 256) (95% CI for the difference was 17.0, 35.4). The prevalence of neutralizing poliovirus antibodies was slightly lower for Easterners for all three types: type 1—82.0 percent vs 89.6 percent, type 2—98.1 percent vs 98.5 percent, type 3—83.2 percent vs 86.6 percent. The prevalence of anti-HAV antibodies was substantially higher for subjects of lower SES (67.3 percent of 171 vs 32.5 percent of 286; 95% CI for the difference 25.3, 44.2) whereas the prevalence of neutralizing poliovirus antibodies was greater for higher SES (89.5 percent of 286 versus 78.4 percent of 171; 95% CI for the difference 4.1, 17.5). In multiple logistic regression analysis (Table 1), low SES and Eastern origin were positively associated with the presence of anti-HAV antibodies after adjusting for education and sex. For type 1 poliovirus, high SES was positively associated with higher antibody titers after adjusting for the other variables.

TABLE 1—Multiple Logistic Regression Adjusted Odds Ratios (with 95% confidence intervals) for the Association between the Presence of Anti-Hepatitis A Antibodies and Neutralizing Poliovirus Type 1 Antibody Titers >1:4 with Sociodemographic Variables in 18–19 year-old Jews in Israel Examined in 1987

	Anti-HAV Antibodies	Poliovirus type 1 antibodies
Variable	Odds ratio (95% CI)	Odds ratio (95% CI)
Sex (Male = 0)	1.22 (0.81–1.83)	1.22 (0.71–2.10)
Ethnic origin (West = 0)	2.29 (1.52–3.46)	0.63 (0.35–1.12)
Years of education (<12 yr = 0)	0.83 (0.46–1.50)	1.42 (0.70–2.89)
Socioeconomic status (High = 0)	3.75 (2.31–6.09)	0.40 (0.22–0.74)

CI = Confidence interval

Discussion

The higher prevalence of anti-HAV antibodies in 18–19 year old Jews of Eastern origin compared with those of Western origin, found in earlier studies,[1] has persisted. The prevalence was also found to be independently higher in those of lower SES. This indicates continuing differential exposure of subpopulations in Israel to viruses transmitted by the fecal-oral route, possibly due to spread among children particularly in large families.[2,5]

The associations of SES and ethnic origin with neutralizing poliovirus antibodies were opposite to those found for HAV. This finding would tend to exclude any significant natural exposure to wild poliovirus. The lower prevalence of immunity against polio among those of Eastern origin and lower SES may be due to variation in immunization coverage in different segments of the population[6] or differences in the uptake of oral poliovaccine due to interference by concurrent gastrointestinal infections.

The findings in the present study suggest that subgroups in this population who are more susceptible to HAV infection are less likely to have high levels of neutralizing poliovirus antibody titers. Thus while HAV appears to be widely transmitted under lower socioeconomic conditions, immunity against poliovirus in Israel over the past 20 years appears to have been determined primarily by compliance with vaccination. If the new HAV vaccine currently being tested becomes routine in childhood, immunity will be determined mainly by vaccine compliance.
